OFFICERS OF THE AMERICAN MEDICA ASSOCIATION—1914-1915

GENERAL OFFICERS

PRESIDENT—VICTOR C. VAUGHAN	Ann Arbor, Mich.
PRESIDENT-ELECT—WILLIAM L. RODMAN	Philadelphia
FIRST VICE-PRESIDENT—D. S. FAIRCHILD	Clinton, Ia.
SECOND VICE-PRESIDENT—WISNER R. TOWNSEND	New York
THIRD VICE-PRESIDENT—ALICE HAMILTON	Chicago
FOURTH VICE-PRESIDENT—WILLIAM E. DARNALL	Atlantic City
EDITOR AND GENERAL MANAGER—GEORGE H. SIMMONS	535 N. Dearborn St., Chicago
SECRETARY—ALEXANDER R. CRAIG	535 N. Dearborn St., Chicago
TREASURER—WILLIAM ALLEN PUSEY	Chicago

BOARD OF TRUSTEES

M. L. Harris, Secretary	Chicago, 1915
W. T. Councilman, Chairman	Boston, 1915
T mas McDavitt	St. Paul, Minn., 1915
N. Grant	Denver, 1916
k J. Lutz	St. Louis, 1916
r Dowling	Shreveport, La., 1916
ip Marvel	Atlantic City, 1917
ilip Mills Jones	San Francisco, 1917
Sarles	Sparta, Wis., 1917

JUDICIAL COUNCIL

E. Moore	Minneapolis, 1915
ubert Work	Pueblo, Colo., 1916
George W. Guthrie	Wilkes-Barre, Pa., 1917
A. B. Cooke	*Los Angeles, Cal., 1918*
lexander Lambert, Chairman	New York City, 1919
lexander R. Craig, Secretary	535 N. Dearborn St., Chicago

OUNCIL ON HEALTH AND PUBLIC INSTRUCTION

W. C. Woodward	Washington, D. C., 1915
H. B. Favill, Chairman	Chicago, 1916
Walter B. Cannon	Boston, 1917
W. S. Rankin	Raleigh, N. C., 1918
H. M. Bracken	Minneapolis, 1919
Frederick R. Green, Secretary	535 N. Dearborn St., Chicago

COUNCIL ON MEDICAL EDUCATION

George Dock	St. Louis, 1915
W. D. Haggard	Nashville, Tenn., 1916
James W. Holland	Philadelphia, 1917
H. D. Arnold	Boston, 1918
Arthur D. Bevan, Chairman	Chicago, 1919
N. P. Colwell, Secretary	535 N. Dearborn St., Chicago

COUNCIL ON PHARMACY AND CHEMISTRY

O. T. Osborne	New Haven, Conn., 1916
Torald Sollmann	Cleveland, Ohio, 1916
M. I. Wilbert	Washington, D. C., 1916
Reid Hunt	Boston, Mass., 1917
J. H. Long	Chicago, 1917
Julius Stieglitz	*Chicago, 1917*
David L. Edsall	Boston, 1918
R. A. Hatcher	New York City, 1918
A. W. Hewlett	Ann Arbor, Mich., 1918
John Howland	Baltimore, 1919
Henry Kramer	Philadelphia, 1919
C. L. Alsberg	Washington, D. C., 1919
John F. Anderson	Washington, D. C., 1920
F. G. Novy	Ann Arbor, Mich., 1920
George H. Simmons, Chairman	Chicago, 1920
W. A. Puckner, Secretary	535 N. Dearborn St., Chicago

SECTION OFFICERS

PRACTICE OF MEDICINE.—*Chairman*, Thomas McCrae, Philadelphia; Vice-Chairman, John L. Dawson, Charleston, S. C.; Secretary, Roger S. Morris, Clifton Springs, N. Y.

SURGERY, GENERAL AND ABDOMINAL—Chairman, Charles H. Peck, New York; Vice-Chairman, Wallace I. Terry, San Francisco; Secretary, E. S. Judd, Rochester, Minn.

OBSTETRICS, GYNECOLOGY AND ABDOMINAL SURGERY—Chairman, Thomas S. Cullen, Baltimore, Md.; Vice-Chairman, George B. Somers, *San* Francisco; Secretary, Brooke M. Anspach, 119 S. 20th St. Philadelphia.

OPHTHALMOLOGY—*Chairman*, E. C. Ellett, Memphis; Vice-Chairman, John A. *Donovan, Butte, Mont.; Secretary*, George S. Derby, 7 Hereford St., Boston.

LARYNGOLOGY, OTOLOGY AND RHINOLOGY—Chairman, Noral H. Pierce, Chicago; Vice-Chairman, Ross H. Skillern, Philadelphia; ecretary, *Francis P. Emerson, 520* Commonwealth Ave., Boston.

DISEASES OF CHILDREN—Chairman, Lawrence T. Royster, Nork, Va.; Vice-Chairman, Albert W. Myers, Milwaukee, Wis.; Secre-, F. P. Gengenbach, 1434 Glenarm St., Denver.

HARMACOLOGY AND THERAPEUTICS—Chairman, R. A. her, New York; Vice-Chairman, J. R. Arneill, Denver; Secretary, Wilbert, 25th and E Sts., N. W., Washington, D. C.

PATHOLOGY AND PHYSIOLOGY—Chairman, A. J. Carlson, Chicago; Vice-Chairman, L. B. Wilson, Rochester, Minn.; Secretary, F. P. Gay, University of California, Berkeley, Cal.

STOMATOLOGY—Chairman, F. B. Moorehead, Chicago; Vice-Chairman, Arthur D. Black, Chicago; Secretary, Eugene S. Talbot, 31 N. State St., Chicago.

NERVOUS AND MENTAL DISEASES—Chairman, F. X. Dercum, Philadelphia; Vice-Chairman, H. G. Brainerd, Los Angeles; Secretary, G. A. Moleen, Mack Bldg., Denver.

DERMATOLOGY—Chairman, Howard Fox, New York; Vice-Chairman, A. Ravogli, Cincinnati; Secretary, H. H. Hazen, The Rochambeau, Washington, D. C.

PREVENTIVE MEDICINE AND PUBLIC HEALTH—Chairman, C. *Hampson Jones, Baltimore;* Vice-Chairman, Eugene R. Kelley, Seattle; Secretary, O. P. Geier, Ortiz Bldg., Cincinnati.

GENITO-URINARY DISEASES—Chairman, Granville MacGowan, *Los Angeles; Vice-Chairman, Edward Martin, Philadelphia;* Secretary, Louis E. Schmidt, 5 S. Wabash Ave., Chicago.

HOSPITALS—Chairman, Winford H. Smith, Baltimore; Secretary, John A. Hornsby, Tower Bldg., Chicago.

ORTHOPEDIC SURGERY—*Chairman, Nathaniel Allison*, St. Louis; Vice-Chairman, Russell A. Hibbs, New York; Secretary, Emil S. Geist, 614 Syndicate Bldg., Minneapolis.

ARE INSTITUTIONS FOR INFANTS NECESSARY? *

HENRY DWIGHT CHAPIN, M.D.
NEW YORK

In considering the best conditions for the relief of acutely sick infants and for foundlings or abandoned babies, two important factors must always be kept in mind: (1) the unusual susceptibility of the infant to its immediate environment, and (2) its great need of individual care. The best conditions for the infant thus require a home and a mother. The further we get away from these vital necessities of beginning life, the greater will be our failure to get adequate results in trying to help the needy infant. Strange to say, these important conditions have often been overlooked, or, at least, not sufficiently emphasized, by those who are working in this field.

The subject naturally divides itself into two branches — the treatment of the acutely sick infant in a hospital, and the care of the foundling or abandoned infant in an asylum.

We will first consider the hospital. An important point to emphasize is that the stay of an infant in a hospital should be as short as possible. The reasons for this are obvious to those who have had much experience along this line. Unless the infant is quickly discharged after the acute symptoms have subsided, there is nearly always a slow but progressive loss of weight which bears an inverse ratio to the age, being especially marked under six months. If this atrophy gets beyond a certain point no change of environment or food will save the patient.

Another danger consists in the spread of specific infections, such as diphtheria, pertussis and the exanthemata. A child may be admitted in the late incubation period, and, if so, is apt to involve many others. These infections may also be brought by mothers or other visitors, acting as carriers. It is now considered that these diseases are spread by contact rather than by aerial transmission, hence the nurses and the children themselves may spread the poison from one to another. When any one of these diseases gets a foothold in an institution it is hard to stamp out the trouble without discharging all the patients in the affected ward, cleaning up the place and starting fresh with new cases. Otherwise, one patient after another will gradually succumb to an exposure from others who may be in the period of late incubation or early invasion. Measles and pertussis are particularly to be mentioned in this connection. Young children with nasal catarrh, enlarged tonsils or adenoids may harbor diphtheria bacilli that remain latent, which accounts for their being attacked without apparent hetero-infection, or, if not succumbing themselves, spreading the disease to others.

Perhaps the greatest danger in keeping sick infants long together, comes from the ordinary ward infections. The mucous membranes usually bear the brunt of these infections. We may thus have rhinitis, pharyngitis, tonsillitis, otitis media, bronchitis, bronchopneumonia and vaginitis. The latter is nearly always specific. It is generally the infants who have been longest in the hospital who succumb to these cross infections. The pneumococcus and streptococcus seem to cause most of the trouble, although, in certain seasons, the influenza bacillus is also very active. Hospital babies show a poor resistance to added infections; their immunizing power against bacteria and other infections seems to be largely lost after a certain length of time in an institution. The infants must thus be discharged at just the right time, when the acute symptoms have subsided and before the cachexia of hospitalism has had time to develop. In a word, in order to insure a good convalescence the infant must be kept in a hospital for only a short time; it must be carefully guarded from auto- and hetero-infection while there, and, finally, sent out to recuperate under as favorable conditions as possible.

I do not believe that the multiplication of infant's hospitals through the country should be encouraged. When infants need hospital care it had better be in small units. The dangers of cross infection must be guarded against by the most skilful nursing as well as by working in small units. There should be one good nurse to three or four sick infants so that there may be a chance effectually to apply the principles of aseptic nursing. Particularly at night, the nursing is too often ineffective from not having enough nurses in attendance. Large wards and large institutions are undesirable as far as the infant is concerned. Atrophic infants with chronic indigestion and malassimilation should never be treated in a hospital. A baby with marasmus will rarely live long in an institution. It is interesting in this connection to glance at the recent action of the Massachusetts Infant Asylum. This institution had developed two rather distinct branches of work — (1) the care of sick babies in its hospital at Jamaica Plain; (2) the placing of well babies at board in private families under the supervision of trained nurses. Later, a department for looking after unmarried mothers and a wet nurses' directory were added. As it seemed wise to revise this wide field of service, the hospital was discontinued and an arrangement made with the Boston Dispensary by which a certain number of beds were retained for babies who might need hospital care before going to board, or such as become sick while at board. The hospital feature of the work was thus reduced to a small unit and the boarding out system emphasized and enlarged. This is a step in the right direction. That more can be accomplished with sick infants by home treatment than has ordinarily been supposed, even in severe cases, provided proper nursing can be furnished, is shown by the figures in the accompanying tabulation, which have been furnished me by the Henry Street Settlement, New York:

---

* Read at the Fifth Annual Meeting of the American Association for Study and Prevention of Infant Mortality, Boston, Nov. 12, 1914.

RESULT OF HOME TREATMENT OF SICK INFANTS

PNEUMONIA				
Birth to 2 years	**1910**	**1911**	**1912**	**1913**
Cured	986	1,251	1,423	1,596
Died	114	181	177	206
Total	1,100	1,432	1,600	1,802

DIARRHEAL DISEASES				
Birth to 2 years	**1910**	**1911**	**1912**	**1913**
Cured	249	339	263	273
Died	30	40	27	25
Total	279	379	290	298

As these figures run through a series of years, they should form a fair general average, and it is doubtful if any hospital can furnish as good results. They were all cared for at home and attended by their own physicians, but skilfully and carefully nursed by the trained nurses from the Settlement. If necessary, several visits a day were made until convalescence was fully established.

When home attention is impossible and the hospital care required, the best results will be obtained by an early discharge with a proper "follow-up" system bv a competent nurse. In this way the best and most permanent results will be obtained.

The next aspect of this question concerns the care of foundlings or abandoned infants in institutions. There is a sharp distinction to be made between hospital care for the acutely sick infant who cannot get proper home treatment, and the ordinary infant asylum. Both have high death-rates, but the latter starts and deals with a well, or comparatively well, baby, who gets sick or loses vitality during its stay in an institution. This makes a radical difference. I believe the plan of collecting babies in institutions should be abandoned, as, on the whole, doing more harm than good. Not only is the mortality under this system very high, but the surviving infants are rarely strong and healthy. In spite of good intentions and care in management, too often these institutions produce or aggravate the very conditions they are supposed to prevent. The danger of institutional care to infants is in inverse proportion to their age, being very great under one year and diminishing as the children grow older. This experience is world-wide, and it seems strange that more energetic steps have not been insisted on, especially by the medical profession, in the line of abandoning these old and futile methods. It is fair to state, however, that some of these institutions are waking up to different plans of action. In a historical sketch of the Foundling Hospital of London, it is stated that in 1756 a basket was hung at the gate in which children were deposited after ringing a bell. It is naively added that of 14,934 children received during three years and ten months, no less than 10,389 perished in early infancy. It is interesting to note, by contrast, that the infants on reception are now placed out to nurse with cottagers in the Kent or Surrey districts under the superintendence of medical officers and are returned to the hospital about the age of five. During 1910, 48 infants were received, of whom only two died under one year, and one under two years after being boarded out in the country.[1]

In a personal letter from the general secretary of Dr. Bernardo's Homes, the largest charity in England dealing with infants, the following statement is made:

> Years ago we established a large institution especially for babies, called our Babies' Castle. Accommodation was provided for 100 babies. The place was beautifully designed and perfected in every detail, but we found that the babies did not thrive and eventually we had to board them out and use the institution in question for those who were a little older. Our experience leads us to the conclusion that a large segregation of babies under one roof is fatal to their well-being and health, however carefully and well they may be looked after. . . . We do not hesitate to say that if a certain number of babies were first of all to be boarded out under good conditions and then segregated under one roof, it would be found that the death-rate would be four times increased in a year or two.

In a minority report of the British Royal Commission on Poor Laws, 1909, it is stated that the mortality among infants in the poor law institutions is between two and three times greater than that found in the general population. It is said:

> Out of every 1,000 babies born in the population at large, 25 die within a week and 132 are dead by the end of the first year. For every 1,000 children born in the poor law institutions, 40 to 45 die within a week, and, assuming the mortality among those who are discharged to be the same as those remaining, no fewer than 268 or 392 will be found to have died by the end of the year, the number varying according to whether we take the experience of the poor law institutions for legitimates or for illegitimates in the metropolis, or elsewhere. . . . The excess of infantile mortality in the poor law institutions is actually greater at the ages between 1 and 6 months, than during the first month of life. . . . It may well be that human infants, like chickens, cannot long be aggregated together, even in the most carefully devised surroundings, without being injuriously affected.

The facts learned by many years of observation and experience on this problem do not seem to be sufficiently appreciated by many in this country. If so, the large asylums and institutions for the care of foundlings and abandoned babies, would be abolished, with a consequent lowering of the infantile death-rate. In a monograph issued by the Division of Child Hygiene of the New York Board of Health, it is stated that during 1910, 42 per cent. of the total deaths of babies under 1 year of age in the Borough of Manhattan took place in institutions (inclusive of both foundling asylums and general hospitals).

In order to get a general idea of the usual death-rates in institutions that house many infants, I made a study of the statistics of ten of these asylums located in different cities as follows: New York, Buffalo, Boston, Providence, Philadelphia, Baltimore, Washington, Detroit, St. Louis and New Orleans. The time covered varied from four to twenty years, taking the shortest and longest intervals. The rates were based on the ratio between yearly admissions and deaths and were as follows: 53.17 per cent.; 40.6 per cent.; 40 per cent.; 60 per cent.; 31.7 per cent.; 75 per cent.;

---

[1] Report of Foundling Hospital, London, 1910.

65.8 per cent.; 47.7 per cent.; 36.1 per cent.; 49.5 per cent. In all but one of these institutions the deaths included all infants under 2 years. As the greatest mortality is under 1 year, the showing would be worse if restricted to this age. The following figures taken from one of these institutions exemplify this point: During 1907, 320 were admitted; of these, 147 died under 1 year and only 18 between 1 and 2 years. During 1908, 417 were admitted, and of these, 113 died under 1 year, and only 12 died between 1 and 2 years.

There is no doubt that the figures cited above give a fair average of the mortality when young infants are collected together in numbers and treated in mass. The high mortality is not so much due to lapses in care or details in management as to the system itself, which fails because it is wrong. As a contributing cause, however, it may be mentioned that rarely, if ever, is sufficient individual care given to infants in institutions. As a result, the condition of those who live is apt to be decidedly below the proper development for the age. It is only fair to say that many babies sent to these asylums are in poor condition from neglect and hardship — sometimes even moribund — but still it is equally true that a very much larger proportion could be saved by a different method of handling them.

This consists in placing them in individual homes where the many risks and dangers of the institution will not exist, even though the domicile be crude and rough. The baby will do better here in the long run than in the most immaculate ward, but visiting and watching will be required. The full benefits of boarding out cannot be obtained without proper and continuous oversight, preferably by a trained nurse. This constant supervision is rarely carried out as it should be under the direction of a physician. Thus in one institution, about 700 boarded-out babies are looked after by only four visiting nurses. In this case, it is manifestly impossible to be sure that the babies are receiving the proper medical and hygienic care.

Boarding out must be more systematized and the same detail and routine that are usually employed in institutional work should be applied here. Twelve years ago I instituted a plan of boarding out atrophic or abandoned babies in which the following features were emphasized: (1) Boarding out in a certain district of the country noted for its healthful conditions. (2) Constant attention to diet and hygiene on the part of a physician and nurse who are thoroughly familiar with this class of cases and competent to deal with them. (3) The infants are kept as long as necessary, until feeding is regulated and digestion and assimilation are improved sufficiently to result in an increase in weight. The work is kept up during the whole year and not limited to certain seasons. (4) The training in a given neighborhood of a number of foster mothers, who, by constantly taking these infants into their homes, become fairly expert in handling them under conditions totally unlike those offered by the best institutions and far superior to them. This work has been in successful operation ever since under the control of the Speedwell Society at Morristown, N. J.

This plan can be employed in any place, with such variations as may be required by the special locality. Thus in a large city it may be best to work in distinct districts which can easily be overseen by some one familiar with the neighborhood and its people. This means a more intensive working in many small fields, but all cooperating in a common system. A few small collecting stations that would act as clearing houses can take the place of the large institutions and furnish the doctors and nurses necessary to carrying on the work. A vast field can thus be covered, but the actual work must be done in small units, each represented by a certain district or locality. Relief will thus be instituted along the lines of family life, with individual supervision, instead of the collective life with institutional methods.

The unit of civilization is the family which offers the healthiest physical environment. The most susceptible member of the family to all external conditions is the infant. When transplanted from natural and normal conditions, the little ones quickly droop and suffer most. We must see to it that relief is afforded in the most natural and effective way to these unfortunates who come under our care. For this reason the infant asylum must go. Cottages must take the place of barracks. An increased knowledge of the real needs of infant life will not tolerate the old methods much longer, for a larger and wiser human spirit is at work on these problems, which is not content to put up with evils that can be avoided. If the present workers in this field will not improve their methods, then some future generation with wider vision, truer courage and broader human feeling will accomplish this needed reform.

EXPERIENCES OF THE NEW YORK HEALTH DEPARTMENT IN TYPHOID IMMUNIZATION

L. I. HARRIS, M.D.
Assistant to Director, Bureau of Infectious Diseases

Case Reports by Morris L. Ogan, M.D.
Chief, Division of Typhoid Fever

NEW YORK

Preventive medicine, despite its brilliant advances in recent days, has met momentary checks, when, as happens from time to time, some apparent instances of its failure to protect from disease have come to light. That element of our lay population which suffers from constitutional timidity and which can be induced only with difficulty, if at all, to adopt the teachings of this newest and most helpful branch of medicine, jumps eagerly at these apparent examples of failure. It makes them serve as justification for relapsing into the helpless and fatalistic attitude toward disease which has come down through the centuries from the dark ages. These particular instances of the so-called miscarriages of prophylactic medicine are trumpeted far and wide and marshaled to serve as evidence against its value, long years after impartial scientists have disproved all criticism and vindicated the signal virtues of this newest department of medical science.

Error and hasty and mistaken conclusions die as hard to-day as ever in the history of scientific progress. In common with every method of treatment that has ever been inaugurated, antityphoid prophylactic treatment has been opposed at each step of its progress by criticism which has sometimes been ignorant, or unscholarly, or malicious, or even all of these. Russell has already paid his compliments to these groups. This study of antityphoid immunization is therefore offered to answer unsound criticism as recently expressed in connection with a series of cases that received conspicuous notices in the New York press. Also it aims to give to those general practitioners who have read the necessarily insufficient and confused comments on these cases in the lay press and even in some of the medical journals a knowledge of facts interpreted scientifically, that they may in their praiseworthy office as teachers be reassured and reinforced in their belief in the value of this protective measure, and may impart with renewed enthusiasm and conviction the full measure of their belief to their pupils—the public.

THE EARLY HISTORY OF ANTITYPHOID VACCINATION

Almost simultaneously in 1896, Pfeiffer and Kolle in Germany, and Wright of Netley, England, published the results of experiments in the prevention of typhoid fever by vaccination with *Bacillus typhosus* killed by heat.

For several years preceding, a group of workers including Dunbar, Fränkel, Simmonds and Stern, had been occupied with the problems of immunology in typhoid fever. Wright made an extensive application of these experiments, vaccinating large groups of men in the British army. His results were not as favorable as had been expected, and the procedure met a setback until Leishman, who had been working with Wright, again essayed the use of this prophylactic measure on a large scale on the men in the Indian service of the British Army. He had concluded that their failure to achieve the success they had anticipated in their first trials was due to a superheated vaccine. This fault was corrected and Leishman's work gave a new impetus to those interested in the subject.

When, subsequently, Wright announced his theory of the negative phase, and the increased risk of infection with typhoid fever, during the period of this phase, progress for a time was again checked. The cumulative, practical experience of Leishman, however, enabled him to refute this theory most emphatically, and to prove conclusively that whatever force it had was more theoretic than real, and "that the most important evidence must come from actual practice, rather than from laboratory experiment." Indeed, Pfeiffer and Friedberger disproved this in laboratory tests on guinea-pigs, as did Leishman in 100 cases at the Baring asylum. Wright himself since 1909 has receded from this position to a very great degree.

In 1911, Major F. F. Russell, than whom there is no more competent authority on this subject in this country, had so far advanced its use among 20,000 men in the United States army that he could assert of those using it that "we knew that the preparation we were using was harmless; we knew too that it caused few severe reactions in *healthy persons,* and that no vaccination, however severe the immediate reaction may have been, had been followed by permanent injury to the individual; and *further that by all laboratory tests the immunity conferred was identical with and equal to that remaining after typhoid fever.*"* The brilliancy of the results achieved by Major Russell at San Antonio, and subsequently, on an even larger scale in the army, results which now have become almost classical, led to the enactment of the compulsory antityphoid vaccination law by the United States government.

In France, in 1913, a similar law was passed, making vaccination against typhoid fever compulsory in the French army.

Fully 85 per cent. of the men in the Indian service of the British army have been vaccinated, although no legal compulsion has been employed by the British government.

In the years that have elapsed since 1896, the evidence of the value of this measure is undoubted, and has grown overwhelmingly; so that when the death-rate in the United States was 16.5 per hundred thousand, that in the United States army during 1912 was 0 per hundred thousand. Further examples selected *from this accumulated testimony, as they bear on the* analysis of our cases, will follow. Well has Russell said, "Our experience since 1909 has left no doubt about the success of antityphoid vaccination in the army and navy. The measure has come to stay."

THE VACCINE—DESCRIPTION AND MODE OF PREPARATION

The prophylactic injections that have been in use have been differently prepared by the various men who have administered them: Leishman in the British army and Russell in America, as well as most other Americans who have employed this procedure, have used a single strain (the Rawlings strain) which is of low virulence. The French prepare a polyvalent vaccine of as many as ten strains, consisting mainly of those found in the neighborhood where an outbreak of typhoid exists. Even in America, some, like Hunt in Troy, Pa., have employed a polyvalent vaccine in which has been included the *B. paratyphosus* A, and *B. paratyphosus* B of Gaertner. Needless confusion in the minds of those not familiar with this subject has been caused by the description of these and a variety of other preparations of vaccine.

Metchnikoff and his pupil, Besredka, for instance, have used a vaccine consisting of an emulsion of living typhoid bacilli sensitized by antityphoid serum. Up to 1913 this vaccine, first employed on chimpanzees, was injected into 800 persons in an institution, without any case developing after its use. One soldier in Africa so treated died of typhoid fever, but Metchnikoff explains this as being due to a dose that was entirely too small. Also, forty-eight patients with pronounced typhoid fever were treated with this vaccine. But the consensus of opinion is that aside from the danger of producing carriers, it is far safer to use the sterilized single Rawlings strain of low virulence, which has proved so brilliantly effective in England and the United States.

Chantemesse has produced an antityphoid serum obtained from horses, which has not been approved of by others.

The New York Board of Health vaccine conforms in every particular but one to the army vaccine; the exception being that phenol (carbolic acid) has been substituted for trikresol as a preservative, because of the lessened pain caused by its injection.

The culture used by the Department of Health is prepared at its Research Laboratory and is made as follows:

> "A laboratory culture of typhoid bacilli which has lost much of its virulence through long artificial cultivation is used. Large surfaces of agar in Blake bottles are inoculated from fresh agar cultures. After twenty-four hours' growth

---

* Italics, the author's.

at 37 C. the bacteria are washed from the surface of the agar with normal salt solution. The suspension is then standardized by counting the bacilli by the Wright method. This is done by mixing an equal part of blood and the bacterial suspension. Smears are made from this mixture and stained. The number of bacilli and red cells are then counted under the microscope in about twenty-five fields. When the proportion between the two has been determined, the number of red cells per c.c. being known, the number of bacilli per c.c. can then be estimated; this suspension is then heated one hour at 56 C., to kill the bacilli. After heating, the sterility of the suspension is tested by inoculating generous amounts into media and incubating these under aerobic and anaerobic conditions. If no growth occurs, 0.25 per cent. of carbolic acid is added to the suspension which is diluted with 0.25 per cent. carbolic acid in normal saline solution so that one c.c. contains the appropriate dose. It is then bottled for distribution."

CASE REPORTS AND COMMENTS

Whenever we add to the sum of our knowledge and experience, we describe a larger circle to embrace the new as well as the old, and so in this study, even if we contribute little that is essentially new, we believe it well in what follows to include a review of much that has gone before, so that a comprehensive and better correlated picture may the more vividly appear.

In the following are presented the histories of the cases whose atypical features offer several problems of interest, and which have prompted this survey of the work of the New York Department of Health in the field of antityphoid prophylactic treatment.

It will be noted that they fall into four classes:

Class 1. In which death has been attributed to antityphoid inoculation, and was really due to another cause, the prophylactic treatment being a mere coincidence.

Class 2. Severe reactions within a few hours after treatment.

Class 3. In which immunization was partial and insufficient, the patients having been long exposed and already in the stage of incubation when treatment was begun.

Class 4. In which a complete course of prophylactic treatment failed to give immunity, and was followed after a relatively short interval by an attack of the disease.

CLASS 1. COINCIDENCES

CASE 1.—C. P., aged, 25, a member of the National Guard, received three injections of antityphoid vaccine in January, 1914. He reacted very moderately to these injections, and for several weeks thereafter continued in good health. Early in March, that is, two months after immunization, he became ill, and the physician who attended him diagnosed his illness as influenza. Just before his death, which occurred March 30, 1914, another physician who was called in diagnosed his case as typhoid fever, and so certified in the death certificate he issued.

Acting on the protest of the surgeon of the regiment to which the patient had been attached, the Department of Health refused to accept the death certificate, and a necropsy was therefore ordered.

April 2 the coroner's physician performed the necropsy, and established the absence of typhoid lesions. The heart was found to be the seat of a malignant ulcerative endocarditis. The skin showed petechiae, and septic infarcts were found in various parts of the body, the kidneys particularly.

This case, in which malignant endocarditis ran such a deceptive clinical course that the physicians in attendance were led to believe they were dealing first with influenza and then with typhoid fever is of a type not unfamiliar in clinical medicine and which frequently remains obscure as to diagnosis until it reaches the necropsy table. Such an erroneous charge against typhoid vaccination as this needs no further refutation. The entire lack of logical sequence between vaccination and the ultimate cause of death is clearly evident.

It is reminiscent, however, of the early history of small-pox vaccination, in which, in the case reported by Broeckerhoff, the Jennerian operation was followed by an illness which was held to be small-pox, and because it resulted in death, seemed, until cleared up by necropsy, an aspersion on vaccination, Death in this instance proved to be due to hemorrhage from a typhoid ulcer, and not to the use of vaccine. So once again, it is interesting to note how consistently history repeats itself.

CLASS 2. SEVERE REACTIONS

CASE 2.—A clerk in one of the divisions of the Department of Health was injected one afternoon with antityphoid vaccine, and it was noticed that on withdrawal of the needle a free stream of dark blood followed. This was interpreted to be due to the puncture of a vein. Not more than half an hour later, he was seized with sudden faintness, his skin became pale and clammy, he complained of headache, showed dulness of intellect, and temperature of 103. These symptoms did not last more than a few hours, and the next day he was up and about ready to return to work. The entrance of the vaccine directly into the venous stream was held accountable for the train of symptoms; but no lasting or serious results remained.

Occasionally an urticarial rash on the chest and abdomen, lasting for a week, has been reported, as has also herpes facialis following these injections.

HISTORIES OF CASES 3, 4, 5, 6 AND 7

Introduction.—Mr. M. arrived at his home in Brooklyn from a business trip through the Southern states, April 23, with a history of illness of ten days' duration. Mr. M.'s physician submitted a specimen of his blood for a Widal test to the New York Department of Health, and on April 25 he was informed that it gave a positive Widal reaction.

At noontime, May 3, in compliance with Mr. M.'s request, the physician administered an immunizing dose of Department of Health vaccine to each of the four presumably well members of the family, consisting of his wife and three children, Ruth, Herbert and Raymond. May 16, Mr. M. died. Mrs. M.'s sister, a Mrs. R., who was present when the prophylactic injections were administered, also received one.

CASE 3.—Mrs. R., the sister-in-law of Mr. M., returned to her home in New York, a distance of at least five miles, and subsequently stated that she had been feeling "very sick" that night. She called no physician to see her. No temperature record or other competent observations were made at the time. She was entirely well in two or three days and able to perform her regular duties. Her case is mentioned because, in association with the four that follow, it served to inspire the criticism and detraction of a few organs of the lay press and, forsooth, of a medical journal too. In common with Herbert M. and Ruth M., whom Mrs. R. brought to her New York home, five miles distant, directly after they had received prophylactic injections, she made a journey, the length and fatiguing nature of which were contra-indicated after immunizing treatment.

Cases 4, 5, 6 and 7 will be briefly mentioned in this class and again in the next, because they illustrate both the phenomenon of a severe reaction, and the futility of preventive inoculation when administered during the period of incubation.

CASES 4, 5, 6 AND 7.—These four cases are those of Mrs. M. and her three children, two of whom, Ruth, aged 4½, and Raymond, aged 6 years, made the long trip to New York with their aunt. Within twelve hours after their injection all are reported as having been "very sick," but temperatures were not taken, and no more precise and detailed clinical notes are on record as to this particular period than is contained in the foregoing incomplete statement of symptoms. Mrs. M. felt well again within two or three days, and continued nursing her husband. The other children also showed but a temporarily severe reaction, with an interval of comparative moderation in symptoms, preceding the conditions to be outlined in that part of the history which is assigned for description in the next class.

In these five cases in which severe reactions were reported to the family physician by the patients themselves, several factors were operative. First, the comparatively long journey to New York made by three of those treated; secondly as will appear from the subsequent history, the M. family so treated were not in good health and probably then already in the period of incubation of the disease.

Of this class, characterized by severe reactions that ue at any time, either immediately after the injection of an immunizing dose of vaccine, or from twelve to forty-eight hours later, much may be said by way of impartial critical comment.

Practically our entire navy has been vaccinated without a single serious result or casualty being noted; and less than 1 per cent. of the men were obliged to rest in bed or be excused from duty as a result of the reaction that followed.

Russell in 128,903 cases observed severe reactions as follows:

After the first dose, 0.3 per cent. in 45,680.

After the second dose, 0.2 per cent. in 44,321.

After the third dose, 0.1 per cent. in 38,902.

Authoritative writers define a severe reaction as one racterized by a temperature of from 103 to 104, malaise, vomiting, diarrhea and chills.

Spooner, in 400 cases, noted severe reactions in 4 per cent.; moderate reactions, consisting of malaise, headache and a temperature of not above 100.5 in 10 per cent., and very slight or absent reactions in 86 per cent.

Hachtel and Stoner of Baltimore immunized 1,326 persons with an absence of symptoms of distinct reaction in 1,160, or over 87 per cent.

Malaise appeared in 775.

Headache appeared in 835.

Muscular pains appeared in 106.

Nausea and vomiting appeared in 60.

Chills appeared in 57.

Temperature rise appeared in 884.

A study of the temperatures gave the following results:

Temperature normal to 101 in 785.

Temperature from 101 to 103 in 82.

Temperature over 103 in 17.

In 1,945 persons on whom they employed a monovalent strain of vaccine, they found that 95.8 per cent. had normal temperature or only a slight rise; in ninety-nine on whom the polyvalent vaccine was used, a normal or slight elevation of temperature was observed in only 80.7 per cent. In other words, severe reactions seem more likely to follow a polyvalent vaccine.

Ravenel of Wisconsin vaccinated 1,900 and noted mild reactions in all but two, who after receiving their third injections had drunk heavily.

Weston, in an experience with 898 persons to whom he administered prophylactic treatment, found a severe reaction after the first dose in 883; a severe reaction after the second dose in 880, and a severe reaction after the third dose in 895.

Of those who received this treatment in the French army, at home and in Africa, severe reactions were noted only in those who were ill or fatigued at the time of the injection, this, despite the fact that a polyvalent vaccine (consisting of ten strains) was employed.

Dr. John W. Brannan, using the New York Department of Health vaccine at Bellevue Hospital on 200 nurses, fifty of the physicians on the house staff, and also on a few male patients in his private practice, reports that of these, only three nurses asked to be relieved of their duties for one day, several interns had a rise of temperature as high as 102, and one doctor had a temperature of 103, with headache and abdominal pain after each of two doses.

Rukke of St. Louis, vaccinating 11,007 cases, giving 33,021 injections in all, noted severe reactions in eighty-seven who, in conformity with practice in the United States army, had received simultaneous smallpox vaccinations. Of these eighty-seven, 50 per cent. had vaccinia reactions or reaction from measles or other infectious diseases. Only one case of musculospiral neuritis developed in an officer as the result of trauma to a nerve. He asserts, on the basis of experience in the families of officers living in the camps, that children bear the inoculation well, even at as early an age as 3 years.

Pensuti, using higher doses of vaccine than those generally employed, vaccinated eight children (from 7 to 12 years of age), without subsequent trouble.

All these citations are to show that the occasional occurrence of a severe reaction has been acknowledged and understood by all competent authorities. The severity of these reactions is determined, as already mentioned, by debility from illness (tuberculosis, etc.), marked fatigue, alcoholism or undue exertion in those subjected to prophylactic treatment. In other instances, injection of the vaccine directly into a vein, or its intramuscular administration, has accounted for very marked reactions.

In civil, as distinguished from military communities, whenever a case in which a severe reaction has appeared has been given publicity, it is usually a professional brother who helps spread misinformation with the benevolent suggestion that a contaminated or improperly prepared vaccine has been responsible for such serious result. This charge, if true, is indeed a grave one. Let us examine it: The heating of the suspension of bacilli that is used in preparing the vaccine, at 56 C. (132.8 F.) and the subsequent inoculations into mediums incubated under aerobic and anaerobic conditions to test the sterility of the suspension, together with the final addition of 0.25 per cent. phenol, would surely preclude contamination. The only organisms that might then possibly be present as contaminating ones, would be the tetanus bacillus or staphylococcus. The presence of these organisms could surely be recognized—the tetanus organism by the characteristic symptomatology resulting from its action, and the staphylococcus by a localized infection at the site of injection. From the history of the cases thus far given, and as it subsequently appears, it will be clearly apparent that neither of these contaminations of the vaccine were present.

All those who are acquainted with the character and the organization of the Research Laboratory of the New York Department of Health, will feel assured that the vaccine is prepared with every caution and safeguard against contamination. Moreover, Drs.

Curran, W. S. Hubbard, F. Harnden, C. R. Love and Dudley, of Brooklyn, employed vaccine of the same stock as the foregoing on members of their own families and on private patients without a single severe reaction or untoward result.

CLASS 3. PARTIAL AND INSUFFICIENT IMMUNIZATION

The history of Cases 4, 5, 6 and 7 is resumed under this classification because after the severe reaction caused by the single injection, which each of these patients received, and the short interval of freedom from complaint that ensued, the symptoms of typhoid fever made their appearance in each case.

CASE 5.—Ruth M., aged 4½ years, became ill May 7, and was brought back to her home in Brooklyn, from New York, by her aunt. The temperature became high (about 104) and hovered about that point for a number of days, while signs of severe meningeal irritation supervened, that is, marked opisthotonos, stupor, muscular rigidity and loss of sphincter control—justifying the name frequently applied to typhoid, *Nervenfieber*. Lumbar puncture, performed May 20, proved negative for meningococci, and the spinal fluid was clear and under considerable pressure. A blood count at this time gave the following results: Polymorphonuclears, 41 per cent.; small lymphocytes, 47 per cent.; large lymphocytes, 9 per cent, mononuclears, 3 per cent.

The Widal test showed agglutination in dilution of 1:60 in ten minutes; 1:120 in ten minutes; partial agglutination, 1:500 in ten minutes; complete in thirty minutes; partial agglutination, 1:1,000 in thirty minutes; complete in one hour.

May 22, an examination of the feces showed typhoid bacilli. There was no doubt therefore that this was a case of typhoid fever which became manifest shortly after a single injection of antityphoid vaccine. The patient subsequently made a complete recovery.

CASES 6 AND 7.—The other children, Raymond, aged 6 years, and Herbert, aged 11 years, also developed symptoms of typhoid fever several days after they had recovered from their severe reactions. Raymond's case ran a brief and uneventful course. Herbert had a moderately severe attack of several weeks' duration with a relapse. These two also made complete recoveries.

CASE 4.—Mrs. M., the mother, who had been assiduously nursing her husband until the time of his death, May 16, and then had similarly cared for her children, kept at her work even when initial symptoms of typhoid fever had made their appearance. Like so many ambulatory cases, the date of onset of her illness could not be definitely established. Despite malaise and an increasing feeling of illness she continued her household duties and the care of her children until June 13, when her physician reported her ill with typhoid fever. On June 15 she died of intestinal hemorrhage.

Clearly this unfortunate family continuously and intimately in contact with a typhoid fever case for a number of days, before a single vaccine injection was attempted, had incubated the typhoid bacilli too long to make effective the antagonistic and immunizing power of antityphoid vaccination.

A study of the third class of cases assumes special importance, because it raises the question whether it is a safe and proper practice to vaccinate those who are much exposed in an epidemic, or in intimate contact with typhoid fever cases, in the capacity of medical attendant or nurse. Here too, isolated examples are of no value in helping one to arrive at a judgment of the value of prophylactic treatment, and one must perforce utilize all available records from authoritative sources, and from such cumulative evidence derive one's conclusions.

It was in connection with this type of case that Wright offered his theory of the negative phase, and expressed his disapproval of antityphoid inoculations during the period of its presence. His theory and the arguments in its support were based on laboratory experiments, and when they were first promulgated, many excellent clinicians were persuaded by their apparent validity to oppose such prophylactic treatment during epidemics. A characteristic example is McCrae who, in his article on "Enteric Fever" in Osler's "System," said, "It is evident that it would not be wise to vaccinate during an epidemic, as the procedure apparently makes the individual less resistant to infection for a time."

As has already been stated in a previous section, Leishman in a series of practical tests conducted on 100 individuals exposed at an asylum, made observations that refuted Wright's theoretic views, and in this he was seconded by a goodly number of careful clinicians and laboratory workers. Of the latter, Pfeiffer and Friedbergers' experiments were particularly valuable.

Cullinan of Dublin, a pupil of Wright, inoculated 500 persons at the Richmond asylum during an epidemic of typhoid fever that lasted five months, and only 1.35 per cent. contracted the disease; and those who came down with it were already in the incubation stage. Of the 114 uninoculated nurses, 14.9 per cent. developed typhoid fever.

Spooner inoculated 29 out of 65 persons in a small Vermont town, at a time when 17 had already been brought down by an attack. Of these 29 only one person (3.5 per cent.) contracted typhoid fever, whereas of 19 who had refused vaccination, 5 developed the disease—26.3 per cent.

Hunt, who in 1912 took charge of the situation in Troy, Pa., where an epidemic was in progress, and who, judged by his report at the time, is not an enthusiast as to antityphoid prophylaxis, found 1,343 persons who had been definitely exposed. Of 761 who accepted vaccination and were well at the time of the first injection, a total of 37 (4.86 per cent.) developed typhoid fever. Of these 37 cases, 28 occurred after the first injection, 7 after the second and 2 after the third injection. Contrast with this the 582 who were not vaccinated and among whom 65 (14.28 per cent.) came down with enteric fever. Whatever his deductions from the facts observed may have been, his testimony, taken together with that of others, seems strongly to argue for a decided protective action of the vaccine even in the presence of an epidemic. Even his mortality statistics would tend to confirm one's faith in the value of protective inoculations, for, of the 37 cases that appeared among the vaccinated, there was but 1 death (0.27 per cent.) as opposed to 17 (8.85 per cent.) among the 65 unvaccinated. Hunt takes issue with Spooner, who believed that there was an acceleration of the onset in the infected vaccinated cases. The former contends that the incubation period was prolonged, and the onset consequently delayed until many days after the second inoculation in four cases, and until seven days after inoculation in another case. The evidence which these particular cases furnish strongly offsets, in Hunt's opinion, the prompt appearance of typhoid fever in 11 cases after the first inoculation.

Nor are these by any means isolated instances in which antityphoid vaccination during epidemics gave an excellent account of itself. It has been recognized that the exposure of hospital attendants, nurses, etc.—particularly nurses who do night duty—predisposes them to typhoid fever, in many cases, quite as much as would an epidemic. Observations made on this group, therefore, are of telling value. Also it should be borne in mind in this connection that nurses are known to be many times more liable to contract the disease than are the others of a city's population; Joslin and Overlander of Boston have found that the incidence of this disease is from eight to twelve times greater among them; while Hachtel and Stoner found the rate among this group of workers for five years in Baltimore, 500 per ten thousand nurses and hospital attendants, or from twelve to twenty times greater than in the city generally. Yet at the Massachusetts General Hospital, where immunization was carried out for three years, the morbidity was only 1.4 per cent., or 19 cases in 1,361, even including nurses on night duty. In Baltimore, likewise, the institution of vaccination abolished the disease among the nurses (among 82 nurses during five years who had not been vaccinated, 7 or 8.5 per cent., contracted typhoid fever).

Ravenel, in a small town in which an epidemic was at its height, vaccinated 116 persons, and not one new case appeared thereafter.

Wright and Leishman vaccinated at Maidstone, when an epidemic had attained its maximum intensity, and with success. At Torrington, Conn., of 80 nurses who were employed, 45 accepted vaccination and remained free from the disease, while of 35 who refused the treatment, 3 cases subsequently developed.

Peterson reports that in one house in which the sanitary conditions were of the worst, there were 14 occupants of whom 7 were down with typhoid fever. The remaining 7 were immunized and no further cases developed.

From this summary of statistical data, which could be greatly enlarged on, it must appear that the fear of a negative phase, and the withholding of immunization from those closely in contact with typhoid fever cases, is not grounded on sound and logical reasoning. The experiences of scientific and conservative observers combine to prove the merit of this prophylactic procedure, and should commend it as a duty to those charged with the care of the community's health, wherever and whenever typhoid fever appears in its midst.

Moreover, the freedom with which conservative clinicians in constantly increasing numbers employ the vaccine as a therapeutic measure, to moderate the severity of this disease when already established, and to diminish its mortality rate, should serve to dispose of any distrust of its effects, which still lingers in some quarters. Wright believes that through its use, *the incidence of typhoid fever is diminished about one-half, and the mortality rate still more.* These statements are not to be construed as a support of those who believe in the therapeutic efficacy of the vaccine, for that is still *sub judice.*

Hornor's studies in the therapeutic employment of the vaccine in 40 of 135 cases, while they show no decided advantage from its use as a curative agent, exhibit, however, no evidence that could in any manner be construed as an argument against the safety of its administration. In addition, the restricted scale on which he has employed it cannot make his experience serve as more than a preliminary experimental note. Compared with Wright's extensive experiences, the limitations of Hornor's report can be better understood.

Russell further reports that in the navy, one mild case followed the second injection. Another man at Guantanamo, Cuba, received one dose, and two days later complained of headache, had a temperature of 104.6 and manifested dulness of intellect. In twenty-four hours he became rapidly worse. He died seventy-six hours after admission to hospital, and seven days after vaccination. The necropsy showed that he was at the beginning of the third week of the disease. The infection was one week old when the single dose of vaccine had been administered. Ambulatory cases are notorious for developing severe symptoms late in the course of the disease, and for their high mortality rate.

The case exemplifies strikingly the manifest difficulty of determining in these exceptional instances whether typhoid infection has already gained a foothold, and is like the cases of Mrs. M. and her daughter Ruth, as recorded in the preceding case reports.

In the *Lancet,* W. Broughton-Alcock reports the use of living sensitized typhoid bacilli (in contradistinction to the killed bacilli employed by Wright and Russell) in 750 persons, in whom he found it innocuous.

Major Russell in a report in May, 1914, says, "The conclusion is inevitable that the prophylactic vaccine as used in the army has given almost absolute protection against typhoid fever, without producing untoward effects of any character, showing definitely that the vaccination is both efficient and harmless." Those who make the point of their criticism the failure of vaccine to confer *absolute immunity,* despite the exposure of some patients to exceptionally large doses of typhoid bacilli, or debilitation which has made the body's resistance to the organism ineffective, are unrelenting and unreasonable judges who will be satisfied with nothing less than perfection. Aside from personal idiosyncrasies which may determine failure to produce antibodies, it must be conceded that exhaustion, or the implantation and growth of a virulent strain of typhoid bacilli may have gained too great a headway to be offset by one or more immunizing doses of vaccine. Even small-pox vaccination, the brilliant achievements of which are accepted by scientists, occasionally fails to confer immunity. Likewise, the administration of diphtheria antitoxin may be deferred so long that the body of the patient is overwhelmed by toxins, and no amount of this effective agent can neutralize the effects of the poison; or, if an antecedent exhausting illness makes the body a ready prey to the virulent diphtheria toxins, it outstrips the neutralizing antitoxin, and the patient succumbs. And yet, though not infallible, diphtheria antitoxin, and possibly, too, the prophylactic use of tetanus antitoxin and antirabic treatment, will continue as our most potent weapons in those diseases. There is scarcely a potent therapeutic measure that has not its limitations or contra-indications.

CLASS 4. FAILURE OF IMMUNITY

This class embraces the cases in which a course of immunizing treatment has been completed, and in which the patients are, nevertheless, after a relatively short interval brought down with an attack of typhoid fever. Here opponents of this measure have found a fertile field for criticism. And it would seem to those not familiar with the literature of the subject that in this particular a significant and incontrovertible objection to immunization has been advanced.

Case 8.—Among a group of cases that developed in October, 1913, in a neighborhood on the lower east side, where infection had been spread through the milk supply, there were four cases in an Italian family, affecting the mother, a Mrs. C., and three of her children. Through the visits of two married daughters and their children, three additional cases developed in their respective families. A third married daughter, a Mrs. L., whose history illustrates the theme under consideration, also visited quite frequently but was prevailed on to accept prophylactic treatment. Accordingly, two doses of 500 million (killed typhoid) bacilli each, were administered, on October 15 and 25 respectively. November 6, 1913, a final dose of one billion bacilli was injected. These were administered by the Department of Health representatives. All went well with Mrs. L. and her family until March, 1914, when her four children, each in turn came down with typhoid fever, in the following order: Rocco, aged 10, March 10; Theresa, aged 4, March 19; Louis, aged 8, March 19, and Daniel, aged 12, March 29. Subsequent examination of the stools of the grandmother, Mrs. C., at the Research Laboratory, showed typhoid bacilli. She had been the carrier to whom the infection of these cases was traced.

Mrs. L., aged 30, who was about three and a half months pregnant at this time, nevertheless devoted herself assiduously for a number of days to nursing her children and attending to household duties at the same time, until the children were sent to Bellevue Hospital. Despite the fatigue and weakness induced by her overexertions, she continued daily to visit the children at the hospital. (The children ultimately recovered).

April 1, 1914, subjective symptoms of marked lassitude and headache appeared. These Mrs. L. attributed to her pregnancy and gave them no further heed, although they steadily became worse during the second week. At this time sharp cramps developed in the right lower quadrant of the abdomen and persisted despite active catharsis. For four days prior to April 21, her headache, fever, abdominal pain and vomiting grew constantly worse. April 21 she was admitted to the service of Dr. W. Gilman Thompson of the Second Medical Division of Bellevue Hospital. The Widal was positive and a blood count showed 5,000 leukocytes (polymorphonuclears 78 per cent.). The spleen was enlarged and an atypical roseolar eruption was present. April 24, at about the fifth month of gestation, she miscarried, as pregnant typhoid fever patients so often do, but this had no influence on the temperature or the course of the disease. Dr. Thompson from his clinical study of the case diagnosed it as one of typhoid fever. April 28 she died. It is to be regretted that no blood cultures during life, or from the viscera after death, had been made. At necropsy, characteristic typhoid lesions were found in the bowels. Peyer's patches in the ileum were greatly swollen, indurated, red and showed ulceration; the spleen was considerably enlarged.

The case of Mrs. L. is then one of a series in which a debilitated condition (in this case from pregnancy and the worry and fatigue incident to nursing her three children affected with typhoid) together with a prolonged exposure to exceptionally large doses of typhoid bacilli overwhelmed the defensive powers of the individual and allowed the infective agent to become dominant.

Case 9.—Miss E. G., aged 29, a nurse doing settlement work on the lower east side of the city, was immunized in June, 1913, and though frail of body worked very hard, nursing, among many others, several typhoid fever patients. In April, 1914, she again nursed several patients of typhoid fever, devoting herself with great energy to their care. April 30, 1914—nearly one year after immunization—she noted definitely the onset of malaise, headache and general pains. May 5 she entered the Post-Graduate Hospital with marked febrile symptoms. May 6 a Widal was negative, but a blood culture showed typhoid bacilli. May 11 the Widal was found positive in a dilution of 1:80 (no higher dilutions were attempted). In the meanwhile her temperature at the beginning of the second week showed the typical continuous elevation, varying only between 104 and 105 F. May 20 she died from intestinal hemorrhage.

Case 10.—Miss D., aged 23, a nurse at the Presbyterian Hospital, received three successive doses of antityphoid vaccine prepared at the hospital, July 1, 11 and 22, 1913, respectively. After nursing a particularly severe case she became ill April 27, 1914, with fever, headache, pains in the back and limbs, and sore throat—that is, nine months after immunization. She continued at her work for several days, despite the indisposition caused by the initial symptoms. On May 2 the Widal test was found suggestive in dilution of 1:20, and negative in dilution of 1:100. Again, May 7, the Widal was positive in a dilution of 1:20, and suggestive in 1:100. May 13, typhoid bacilli were found in the blood. Her temperature curve was an atypical one showing fluctuation in the second week between 98.8 and 103.5, reaching 105 at the end of the fourth week, and then continuing its large excursions. After a stormy period of eight weeks she recovered.

Again one turns to the record of Russell's experiences, and there one finds a telling and satisfying answer in quotations from his writings already given, where he says that "by all possible laboratory tests, the immunity conferred was identical with and equal to that remaining after typhoid fever."

To place the problem here presented in different words: If, notwithstanding an attack of typhoid fever, thoroughly authenticated by laboratory and clinical diagnostic tests, there still may follow a second attack of the disease at some later period, even though it is commonly taught and accepted that one attack confers immunity for life, then why should immunity obtained by vaccination be deprecated and tabooed if a like exceptional recurrence follow its practice? That vaccination gives immunity to great masses of those exposed, is most eloquently attested to by the vigorous and severe test it has received in our army and navy among more than 200,000 men. And this should outweigh overwhelmingly the criticism that an occasional exception has evoked. From the literature we shall first cite the reports of recurrences of typhoid fever, and then compare them with the reports of typhoid fever cases subsequent to vaccination, remembering that it is currently held that the latter confers immunity lasting from two to two and one-half years, according to Firth of England. Martha Wollstein, it may here be observed, is quoted as believing in revaccination after one year, though this is contrary to Firth's and Russells belief in a two or two and one-half years' immunity as noted in their extensive experiences in India and the United States, respectively.

1. Some reports of recurrences are as follows:

Dreschfield in over 2,000 cases at the Hamburg General Hospital reports that fourteen were affected twice, and one three times.

In 500 of Osler's cases in which special inquiry was made as to the history of a previous attack, eleven, or 2.2 per cent., were found in which it had occurred.

W. T. Cummins and P. K. Brown found that of 149 of their cases nine had relapses, one of them occurring four weeks after the patient left the hospital; one other patient developed a second attack after six years.

As to relapses, Strümpell reports that they occurred in 9 per cent. of all cases of typhoid fever at Leipsic; Murchison, 3 per cent.; Griesniger, 6 per cent., and Shattuck as high as 16 per cent. McCrae in 28,057 collected cases found 2,493 (8.8 per cent.); while in 172 of his own cases relapses occurred in 11.4 per cent. Why these relapses should occur is a question at once difficult and not in place here to consider, except to indicate that Durham's explanation of the evolution and unexpected dominance of a heretofore subordinate and quiescent strain or family of *Bacillus typhosus* is quoted with approval by McCrae.

2. Directing our attention to the occurrence of typhoid after a complete course of immunization, we find the following instances recorded in the literature:

Russell reported twenty-seven cases of typhoid occurring among the men of our army and navy, with one death, the result of intestinal hemorrhage. Of these twenty-seven cases of infection in vaccinated persons, four cases developed in less than one month after vaccination; eight cases developed within three months after vaccination; six cases developed within six months, and over three months after vaccination; six cases developed within twelve months, and over six months after vaccination; two cases developed within eighteen months, and over twelve months after vaccination; two cases developed within twenty-four months, and over eighteen months after vaccination; in three cases the interval was unknown.

Here again, the relatively long period elapsing between the time of vaccination and the appearance of infection would argue powerfully against the theory of a negative phase, if further argument were needed.

Hunt, as already mentioned in a different connection, among 761 who were vaccinated, found two in whom typhoid fever followed the third injection.

In the Massachusetts General Hospital, 1,361 were vaccinated, and but two cases of enteric fever developed (a morbidity of 0.15 per cent.) against eight cases in 674 non-immunized persons (a morbidity of 1.19 per cent.). At this institution, of the two cases that developed, both were in nurses, one of whom a year after inoculation cared for two patients outside the hospital, and developed a severe attack, but recovered. The other nurse was free two years after vaccination, but then became infected from typhoid material that accidentally entered her mouth.

Here, then, to summarize the results of this review of the literature, are facts obtained from two different angles, which, brought to a focus, show distinctly that whether it is by an attack of typhoid fever, or by the prophylactic injection of killed typhoid organisms, the immunity acquired by great masses of individuals can be safely depended on, in the one case for a protracted period or even a lifetime, in the other case for a period of from two to two and one-half years or even longer.

When it is seen that in those inoculated, a great decrease in morbidity and mortality as contrasted with uninoculated groups of a population results, then indeed is enthusiastic belief in its value justified. Experiences many times multiplied, like those of Wright at Ladysmith, confirm one's faith in its protective power. Of 1,705 persons whom he inoculated, only 2 per cent. contracted typhoid as against 14 per cent. among 10,529 uninoculated persons; and again elsewhere, where of 19,069 inoculated, 266 cases of typhoid (1 in 84.4 persons) developed with a mortality of 17 per cent., while among 150,231, 3,739 cases (1 in 40 persons) developed with a mortality of 25 per cent.

No better statement of the present day attitude on the subject of the possibility of obtaining absolute immunity through antityphoid prophylactic treatment could be given than is contained in a letter of Major Russell written from Vera Cruz to the Department of Health, Aug. 10, 1914, and received after this article had been written. We here take the liberty of inserting quotations from it:

> As you will note (in the article written in June, 1912, in the *American Journal of the Medical Sciences*), there was one fatality among the 27 cases, and that from hemorrhage.
>
> Twenty of the 27 cases occurred within one year of vaccination, probably because of the greater exposure of recruits to all kinds of infection than occurs among older soldiers. *It is evident that the vaccine cannot be expected to give absolute protection, even in the period immediately following it.* To be sure, it does protect in almost every instance, but the exceptions are frequent enough to prevent our claiming absolute protection. There is no perfectly satisfactory explanation of the occasional failure to protect. We know, of course, that clinical typhoid is not infrequently followed by relapse, and that the disease may occur twice in the same person. It may be due to an excessive dose of infectious material, as in milk epidemics, or among nurses, or to the apparent impossibility of obtaining a high degree of immunity in certain persons.
>
> I do not believe we are justified in promising absolute immunity even for a short period; we can state, however, that the chances of infection among vaccinated persons is extremely small and that when infection does occur, the prognosis is decidedly better than among the unvaccinated (1 death in 27 cases).
>
> We feel very confident that the vaccine protects against the average dose of infectious material, but we have always doubted its power to protect against excessive amounts. While it is true that the protection conferred is not absolute, that is no reason for not using it in dispensaries, hospitals and among contacts as much as possible.
>
> Not a single case of typhoid fever has occurred among the troops with whom I am serving, since they were first mobilized in Texas over two years ago; we are not exposed, however, to milk epidemics to any great extent, since the use of canned milk among troops, while in the field, is almost universal.

It is earnestly desired that all experiences of private physicians in this community, along the lines above indicated, be sent to the department that it may cooperate in their investigation and proper classification, with a view to correlating the mass of testimony to serve for future guidance.

The experiences of the New York Department of Health as here offered indicate that in a civic community no conclusive or valuable study, such as of prophylactic antityphoid injections, is possible, unless the Department of Health can serve as a clearing house to which the facts of isolated experiences of individual physicians are sent, and through which they pass as a well-ordered, logically arranged whole.

GENERAL CONCLUSIONS

1. The accurate observations recorded in hundreds of thousands of cases leave no doubt as to the preventive powers of antityphoid vaccination in all but a relatively insignificant few.

2. In those subsequently affected it strikingly decreases the morbidity and the mortality.

3. Severe reactions, if one makes observations from extensive studies (the only correct way), are rare.

4. To avoid severe reactions one must observe carefully several precautions, as follows:

(*a*) Never administer it to any but the healthy.

(*b*) To permit of slow absorption, avoid puncture of a vein, or intramuscular injection.

(*c*) Clean syringe and sterilize the area for injection, using tincture of iodin for the latter purpose.

(*d*) Children especially are to avoid exposure to the sun following treatment.

(*e*) Avoid administering it during the menses or pregnancy.

(*f*) Allow no hard work or indulgence in alcohol after the injection.

(*g*) Avoid reinjecting in indurated areas.

5. Severe reactions have never left permanent injury.

6. When the incubation period has begun, the time for antityphoid immunization has passed. The treatment is preventive of typhoid fever, and not a typhoid antitoxin.

7. Long exposure to overwhelming doses of typhoid bacilli (in those who are in close contact with cases and especially in epidemics), may nullify the immunizing powers of antityphoid vaccine, and an attack may therefore follow one or more injections.

8. Chronic illness (tuberculosis, etc.), as well as debility from other causes, and fatigue and exhaustion as well, predisposes to severe reactions.

9. Injections after intimate and long exposure hasten the onset.

10. For a period of at least two years, and possibly more, immunization is as effective in protecting from an attack of typhoid fever as is a previous attack of the disease itself.

11. Recurrences may follow after a complete immunizing course of treatment, in exceptional instances in which debility and fatigue exhaust the resistant and defensive powers of the body, and when exposure to massive doses of typhoid bacilli exists.

Thankful acknowledgment is made of suggestions and assistance received from Dr. John S. Billings, director of the Bureau of Infectious Diseases of the Department of Health.

1855 Seventh Avenue.

THE PATHOLOGY OF THE MISTAKEN DIAGNOSES IN A HOSPITAL FOR ADVANCED TUBERCULOSIS *

J. EARLE ASH, M.D.
BOSTON

"Progressive medicine recognizes that among the most helpful aids to the advancement of the work of our profession are the critical analysis of errors, either in diagnosis or treatment, the frank discussion of mistakes, and the unremitting investigation of the reasons why procedures in current practice fail."[1] The following confession and analysis of errors is made in this spirit, and further to add its iota of emphasis to the importance of the correlation of clinical and pathologic data. An important purpose of the necropsy is surely lost if it is not observed at least indirectly by the clinician that he may learn of his mistakes or strengthen his convictions.

In the 198 necropsies that have been performed at the Boston Consumptives' Hospital since its foundation, twenty-three cases, or 11.5 per cent., have proved to be non-tuberculous, in so far, at least, that there was no active lesion. The report is not to be construed in any sense as a criticism of the clinical staff of the hospital. It is thoroughly appreciated that under the conditions, in a number of the cases, the diagnosis of tuberculosis was the logical one, and further in their defense it might be stated that seven of the twenty-three cases they recognized ante mortem as being non-tuberculous and five others were under observation only one, two or three days, so that there was no opportunity for close study. They all had been diagnosed tuberculosis, however, by some physician at some time to account for their reference to this institution.

It is not to be supposed that this percentage of error extends to all the cases that have been treated in the hospital. It would be lowered by those cases of undoubted tuberculosis that have been discharged otherwise than dead and further, greater effort has been made to obtain permission for necropsy in those cases of special interest and obscurity, among which have been the majority of the non-tuberculous. It does mean, however, that a total of 1,365 hospital days have been usurped by these proved non-tuberculous from the needy tuberculous of the long waiting list that is always a feature of hospitals of this nature. This is a point of considerable economic importance, not so much to general hospitals as to the special institutions receiving sums of money for the specific purpose of attempting to care for the large group of tuberculous humanity.

These cases are not presented in great detail because of their number, but just those points from the clinical and pathologic protocols are given that are of correlative interest including the clinical diagnosis, color, sex and age. They are grouped and briefly discussed on the basis of the chief pathologic findings.

Case 1 (No. 1346).—White woman, aged 48. Clinical diagnosis, acute pericarditis; fibroid tuberculosis. In hospital but one day. Cough and expectoration intermittently for twelve years. Fever, palpitation and precordial distress on admission. Dulness over left apex; few fine, moist râles through left lung; sibilant on right. Heart enlarged to left; friction rub at apex; pulsus paradoxus. Sputum negative for tubercle bacilli.

Necropsy.—Acute fibrinous pericarditis (pneumococci and streptococci); late stage of a resolving pneumonia; dense contracted scar at left apex, 3 by 2.5 cm.; mucopus in bronchi; syphilis apparent from changes in aorta and liver and the presence of amyloid histologically.

Case 2 (No. 1862).—White woman aged 53. Clinical diagnosis, carcinoma and gangrene of lungs. Patient was in hospital but two days. Seven months before, a carcinomatous breast was removed. Cough began one week later. She raised large amounts of fetid, blood-streaked sputum that was negative for tubercle bacilli. There were several frank pulmonary hemorrhages. Dulness over upper portions of both lungs, and lower posterior of right. Numerous and various râles throughout both sides. In addition, there were signs of cavity in right axilla.

Necropsy.—Unresolved and organizing pneumonia; gangrene and abscesses of lungs; bronchopneumonia and encysted empyema at right base. No carcinoma or tuberculosis.

Case 3 (No. 1925).—White man, aged 38. Clinical diagnosis, pulmonary tuberculosis, revised to unresolved pneumonia. Sudden onset, two weeks before admission, with chills, cough and cyanosis. Signs of consolidation over greater portion of left lung. Pericardial friction rub. Sputum negative for tubercle bacilli.

Necropsy.—Lobar pneumonia; empyema (left chest); purulent pericarditis.

Case 4 (No. 2617).—White man, aged 22. Clinical diagnosis, pulmonary tuberculosis; empyema; gangrene of lung; lumbar abscess. For three months suffered loss of weight and strength; severe cough and abundant sputum, positive for tubercle bacilli on one examination. An empyema was drained surgically and abscesses developed in lumbar muscles and left groin. Dulness over both lungs, especially the right; râles.

---

* From the Pathological Laboratory of the Boston Consumptives' Hospital, Mattapan, Mass.

[1] Deaths Following Anesthesia, editorial, The Journal A. M. A., April 4, 1914, p. 1098.

Necropsy.—Unresolved and organizing pneumonia; chronic empyema and secondary multiple abscesses; general amyloid.

Case 5 (No. 2838).—White man, aged 43. Clinical diagnosis, pulmonary tuberculosis, bronchiectasis; chronic interstitial nephritis. Patient was in hospital but two days. Cough for one month, gradually increasing in severity, at times raising quantities of sputum, occasionally fetid, in which one tubercle bacillus was found; afternoon temperature and increasing prostration. Both lungs were dull throughout and fine and medium moist râles were heard. A trace of albumin, coarse and fine granular casts in urine.

Necropsy.—Unresolved croupous pneumonia in both lungs, with areas of gangrene; ulcerative bronchitis; chronic interstitial and degenerative nephropathy.

Case 6 (No. 2914).—White man, aged 26. Clinical diagnosis, pulmonary tuberculosis; bronchopneumonia; empyema. Eight months before death, was admitted to a general hospital after having suffered a severe chill and pain in right side. From the cough, blood-streaked sputum, marked physical signs in the chest that later developed and the Roentgen ray, a diagnosis of "pneumohydrothorax" was made. A quantity of purulent fluid was drawn from the right chest. Patient was discharged, but later readmitted with same symptoms, the bloody sputum being a more prominent feature. Tubercle bacilli were found in sputum and he was transferred to this institution. While here, he had several frank hemorrhages, and one tubercle bacillus was found after extended search. Signs of consolidation and fluid were still present and the right chest was aspirated on several occasions.

Necropsy.—Chronic adhesive pleuritis of right lung, walling off a large pocket of pus. The lung was entirely denuded of pleura over this area, the parenchyma itself ulcerated, a number of small vessels exposed and rather free communication between empyema cavity and bronchi established. No evidence that this was a tuberculous process could be found either grossly or microscopically. The lung itself showed compression atelectasis. Confluent bronchopneumonia of left lung; early amyloid in spleen, liver and kidneys.

Case 7 (No. 3142).—White boy, aged 22 months. Clinical diagnosis, pulmonary tuberculosis; tuberculosis of bronchial glands. Definite history of pneumonia five months before death, followed by a progressive loss of weight and strength, dyspnea, and hectic temperature becoming more distinctly septic in type. Lungs: Dulness over entire left chest, bronchial breathing in lower half, fine and medium râles in both lungs. After numerous examinations a few tubercle bacilli were found.

Necropsy.—A large, chronic empyema in left chest, compressing lung into a small mass along vertebral bodies. Sinuses through the atelectatic lung drained this cavity into the large bronchi and no doubt transmitted the harsh bronchial breath sounds heard during life. Microscopically, there were found a few young miliary tubercles in the compressed lung, but none in the cavity wall or elsewhere. The right was the seat of extensive hemorrhagic infarction, the emboli arising from a mural thrombus in right auricle that extended through the tricuspid orifice.

Case 8 (No. 3179).—White man, aged 45. Clinical diagnosis, pulmonary tuberculosis (?); abscess of right lung. In hospital but two days. Sudden onset three months before death with chill. Patient developed a severe cough with expectoration. The sputum was fetid for last two months; patient did not stop working, however, till one month later. Three weeks before death, patient developed a severe pain in right side accompanied by marked dyspnea which persisted. Signs of consolidation over entire right lung, posteriorly over left. Sputum negative for tubercle bacilli.

Necropsy.—Gangrenous, non-tuberculous cavity involving practically entire upper lobe of right lung. The cavity was practically filled with masses and strands of necrotic tissue, plugs of which occluded the bronchi, masking the usual signs elicited over a cavity. Middle and lower lobes solid with late gray hepatization, showing small foci of abscess formation and gangrene. Left lung seat of hypostatic pneumonia and edema. Heart dilated.

In this group of cases, one of delayed resolution, three of gangrene and abscess, and three of empyema, all of them the complications of pneumonia, the diagnosis is particularly difficult. The physical signs are so confusing and the subjective symptoms are usually so strikingly like those of advanced tuberculosis that a differentiation in every case seems rather hopeless. Yet this is the very type of the whole series that promises the most favorable result to the proper treatment, particularly in the light of the advances made in chest surgery. To make the diagnosis still more difficult, the onset of the underlying pneumonia is often very obscure, as in Cases 1, 2, 4 and 5. The patient may even continue with his work during the sthenic stage of the infection with the impression that he suffers merely from a "cold," and not give up till the effects of an empyema, abscess, gangrene or some other complication debilitates him. This emphasizes the importance of a close scrutiny of the previous history and suggests that a number of cases of uncomplicated pneumonia must come and go without being recognized.

Case 9 (No. 684).—White man, aged 63. Clinical diagnosis, pulmonary tuberculosis; tuberculous meningitis. Loss of weight and strength for several years; cough with scanty sputum, negative for tubercle bacilli. Dulness over right lung; râles not constant and varying from fine moist to coarse. Dyspnea toward the end and on last day rigidity of neck and Kernig's sign.

Necropsy.—Chronic interstitial nephropathy; chronic myocarditis; general arteriosclerosis; edema and congestion of lungs; moderate chronic bronchitis; cerebral anemia and edema. There was no anatomic explanation for the dulness in right chest.

Case 10 (No. 874).—Man, negro, aged 60. Clinical diagnosis, pulmonary tuberculosis; moderate emphysema; old pleurisy and effusion at left base. Loss of weight and strength, dyspnea and cough for a year. Considerable sputum during final month, positive for tubercle bacilli. Marked dulness over both lungs and numerous coarse râles; cardiac murmurs.

Necropsy.—Chronic fibrous obliterative pericarditis; aneurysm of aorta; left chest, chronic pleurisy, hydrothorax and compression atelectasis; general chronic passive congestion; terminal bronchopneumonia.

Case 11 (No. 938).—White man, aged 56. Clinical diagnosis, pulmonary tuberculosis; pneumothorax; aortic regurgitation; tabes dorsalis. Lost 25 pounds the summer before death. Cough for six months with copious sputum, negative for tubercle bacilli. Dulness over both apices and right base; râles throughout both lungs; subcutaneous emphysema of neck. Death followed a 2-liter pulmonary hemorrhage.

Necropsy.—Large aortic aneurysm that had eroded and ruptured into left primary bronchus. The tabetic symptoms were the result of erosion of vertebrae and pressure on the cord.

Case 12 (No. 1241).—White woman, aged 41. Clinical diagnosis, carcinoma uteri; mitral stenosis and regurgitation; cardiac dilatation. "Pleurisy" one year before death. Loss of weight and strength; intermittent, hacking cough with some expectoration, negative for tubercle bacilli. Lungs practically free; heart enlarged and presented murmurs; uterus irregularly enlarged; acrid vaginal discharge.

Necropsy.—Mitral stenosis and regurgitation; cardiac hypertrophy and dilatation; pleural and peritoneal transudate; uterine fibroids (no cancer).

Case 13 (No. 1461).—White woman, aged 29. Clinical diagnosis, pulmonary tuberculosis; chronic nephritis; mitral stenosis. Pregnant. Cough for five months; moderate amounts of sputum, at times blood-tinged, which was positive for tubercle bacilli. Three months before death was in another institution for tuberculosis. Slight dulness at left apex of lungs; moderate dulness at both bases with a few moist râles after coughing. Presystolic murmur at apex. Patient died after a cesarean section performed on account of persistent headache and vomiting and suppression of urine. Latter contained albumin and casts.

Necropsy.—"Button-hole" mitral valve; pleural effusion with moderate compression atelectasis; chronic passive congestion of lungs and bronchi, mucosa of which was blood-stained; marked glomerular nephropathy. One fibrosed, non-active miliary tubercle was found histologically.

Case 14 (No. 2046).—White woman, aged 58. Clinical diagnosis, chronic pleurisy; mitral and tricuspid regurgitation. "Pleurisy" of four years' standing; slight cough and scanty expectoration since pneumonia one year before death; palpitation and dyspnea more recently. Moderate dulness at left apex of lungs; harsh breathing and leathery squeaks through both sides. Heart enlarged to left, thrill and murmurs over entire area. Sputum negative.

Necropsy.—Right lung presents general, thin, fibrous pleural adhesions; congestion and edema of both. Marked hypertrophy of heart; chronic obliterative pericarditis; "button-hole" mitral; enormous thrombosis of left auricle.

Case 15 (No. 3009).—White woman, aged 72. Clinical diagnosis, pulmonary tuberculosis; pleurisy with effusion; mitral regurgitation. History of pneumonia and pleurisy ten years before death; "bronchitis" eight years later; cough persistent for last year with some sputum, positive for tubercle bacilli. Palpitation and dyspnea on exertion; only occasional rises in temperature. Dulness at both apices and left base of lungs, distant breath sounds over latter. Heart enlarged; systolic murmur at apex. Edema of extremities. Albuminuria.

Necropsy.—Lungs: Chronic circumscribed empyema on right side, pleural effusion on left; compression atelectasis of both lungs; multiple hemorrhagic infarcts of both lungs from emboli from a mural thrombus in right auricle. Hypertrophy and dilatation of heart; very marked focal and diffuse fibrous myocarditis. General arteriosclerosis, passive congestion and senile changes.

This second group is made up of two cases of aortic aneurysm, four of chronic cardiac lesions and one of cardiorenal disease. The patients were all, with the exception of Cases 12 and 13, well past 50 years of age, gave the history of loss of weight and strength, cough and more or less expectoration. Objectively, the confusing factors were the râles, present in all the cases, and signs of fluid in Cases 10, 13 and 15. Well-marked pulmonary congestion and edema and pleural transudate were invariably found to explain the physical signs. Cough in persons past 50 years of age is not unusual and was a prominent feature in several of these cases because of the chronic passive congestion of the bronchial mucosa.

Case 16 (No. 3419).—White man, aged 65. Clinical diagnosis, pulmonary tuberculosis; arteriosclerosis. Alcoholic and specific history. Severe trauma to left chest three years before death. During the last year suffered from pleurisy, and several pints of fluid were aspirated at various times. Loss of weight and strength and cough for two years. Lungs: Flatness over right chest with diminished breath sounds at base; dulness over left lung, bronchial breathing, râles. No fever at any time; sputum negative for tubercle bacilli.

Necropsy.—Malignant leiomyoma (probably primary in prostate) with nodular metastases to left lung, mediastinum, liver, pancreas, suprarenal, skin, etc. Chronic empyema and compression atelectasis on right side. Histologically, there were small foci of caseation in lungs and suprarenal, but no active process.

Case 17 (No. 3071).—White man, aged 57. Clinical diagnosis, pulmonary tuberculosis; laryngeal tuberculosis; chronic alcoholism; exhaustion psychosis. Marked alcoholic history. "Pleurisy" three years before death. Cough and expectoration for last six months; night sweats, dyspnea, hoarseness of sudden onset, pain on swallowing, loss of weight and strength, but no fever. The throat symptoms became the prominent subjective feature. Dulness and bronchial breathing at both apices of the lungs. Tubercle bacilli were found in the sputum. Patient's mental condition required his transfer to the Boston State Hospital, where he shortly died, and to whom we are indebted for the necropsy report.

Necropsy.—Carcinoma of larynx with metastasis to lung, liver, stomach and pancreas. No tuberculosis was found.

Case 18 (No. 2979).—White man, aged 37. Clinical diagnosis, pulmonary tuberculosis; chronic hypertrophic osteo-arthropathy. Beginning with "neuritis" eight years before death, he three years later developed pain, swelling and tenderness of ankles; later involving the other joints of extremities. Irregular thickenings and definite exostoses developed still later, particularly at epiphyses of long bones. A striking feature also was the enormous clubbing of the fingers and toes that subsided considerably in the later months. Three months before death, *signs of consolidation appeared in upper portion of right lung.* There was practically no cough or sputum and no tubercle bacilli were found.

Necropsy.—Chronic hypertrophic osteo-arthropathy; primary carcinoma of right lung with metastasis to brain, periosteum, kidneys, etc.

Case 19 (No. 2734).—Man, negro, aged 59. Clinical diagnosis, pulmonary tuberculosis; right pleural effusion; carcinoma of liver. For three months suffered with pain in the right side and dyspnea on exertion; loss of weight and strength; practically no cough or expectoration; no tubercle bacilli found. Considerable serous fluid aspirated from right chest. *Dulness over entire right lung* and apex of left; few râles after coughing. Definite tumor in epigastrium.

Necropsy.—Right-sided hydrothorax with compression atelectasis of lung; primary carcinoma of liver with metastasis to pancreas, diaphragm, right pleura and mediastinal glands.

Case 20 (No. 2768).—White woman, aged 55. Clinical diagnosis, pulmonary tuberculosis; carcinoma of cervix and vagina; vesicovaginal fistulas; chronic cystitis. Cough for five years; loss of weight and strength. Dulness over upper lobes of both lungs, few fine râles on coughing; signs of cavity in left lower lobe posteriorly. The carcinoma diagnosed by uterine curettings. *Sputum negative* for tubercle bacilli.

Necropsy.—Emphysema of lungs; moderate chronic bronchitis. In left lower lobe posteriorly, corresponding to location of cavity elicited clinically, was a mass of scar tissue 1.5 cm. deep by 2 cm. in diameter, firmly adherent to chest wall. In this mass the bronchi were considerably distended. There was a hard, ulcerating carcinoma of cervix and vagina; two vesicovaginal fistulas; chronic cystitis and ascending pyelonephritis.

In this group are five cases of malignant disease, in Case 18 primary in lung, in Cases 16, 17 and 19 metastatic in lung, and in Case 20 the lungs were not involved in the tumor process. As in the previous group, progressive loss of weight and strength were prominent features of the clinical history. Very definite physical signs were elicited over the chest, of course, in all the cases except the last because of the lung and pleural involvement with tumor.

Case 21 (No. 1546).—White man, aged 71. Clinical diagnosis, chronic cystitis; aortic regurgitation; emphysema; acute appendicitis.

The cystitis was of long standing, following prostatectomy and repeated, careless self-catheterization. Loss of 50 pounds in weight during last two and a half years; cough, with scanty, yellow sputum for last one and a half years, negative for tubercle bacilli. Slight dulness at apices of both lungs; a few râles.

Necropsy.—Chronic bronchitis; hypostatic congestion of lungs; aortic stenosis; chronic cystitis with ascending pyelonephritis; ruptured appendiceal abscess. The loss of weight, cough and expectoration, while in this case the result of the chronic intoxication and heart lesions, *meant only one thing* to the outside physician—tuberculosis.

Case 22 (No. 1591).—White man, aged 40. Clinical diagnosis, pyelonephritis; decubitus; general septicemia. For over two months there had been a loss of weight and strength following typhoid pneumonia. There were no subjective symptoms suggesting tuberculosis and, objectively, merely a few fine moist râles at both bases. The sputum was negative.

Necropsy.—Aside from calcified nodules at the left apex, the changes found were those the result of the toxemia from the pyelonephritis.

Case 23 (No. 1322).—White woman, aged 26. Clinical diagnosis, purulent bronchitis and septicemia (streptococcic); *chronic peritonitis (postpuerperal). Of six months' duration,* with severe pain in left chest; night sweats; loss of weight and strength. Signs of consolidation at left base. Cough and copious sputum negative for tubercle bacilli, but containing many "streptococci." Blood-culture sterile; leukocytes 25,000.

Necropsy.—Actinomycosis of lung, liver and spleen. There was no history of contagion, and the subjective and objective symptoms could easily justify a diagnosis of tuberculosis. The error was a pathologic one, in failing to recognize the organism in the sputum.

It will be noticed that there is a rather significant grouping of these cases pathologically, that twenty of the twenty-three cases fall under three heads: (1) the sequelae of pneumonia, that is, delayed resolution, abscess, gangrene and especially empyema; (2) cardiorenal disease including aortic aneurysm, and (3) malignant tumors, not necessarily of lungs (Table 1).

Because these cases do not form a heterogeneous collection of conditions but are so definitely grouped, it seems that there are lessons to be learned from them and that greater precision in diagnosis is a possibility.

TABLE 1.—CORRELATION OF ANATOMIC DIAGNOSES

	No.	Percentage of Non-Tuberculous	Percentage of Total
Pneumonic sequelae	8	34.5	4
Chronic cardiorenal	5	30.5	3.5
Aneurysm of aorta	2		
Malignancy	5	21.5	2.5
Septicemia	2	13.5	1.5
Actinomycosis	1		
		100	11.5

A very *disconcerting factor with us in this* series of cases has been the number of positive sputa reported. In eight of the cases have tubercle bacilli been found, and the diagnosis of tuberculosis has been made on this basis largely in spite of any doubt that had previously existed as to the true nature of the case. It is safe to say that lesions of sufficient size to discharge bacilli into the sputum were not overlooked. In two of them lesions were found microscopically, but to account for the presence of bacilli in the other six we must assume either a contamination of the patients' mouths or the bottles or a confusion of the specimens and names, a possibility among a large group of patients from whom a number of specimens are being collected. In cases in which the diagnosis is at all doubtful, therefore, a number of sputum examinations should be made, in institutions especially, rather than placing entire confidence in one positive finding.

With the idea of determining whether or not this institution was unique in its high percentage of mistaken diagnoses, and further to see if the distribution of these cases was accidental, letters were sent to a number of institutions caring for the advanced tuberculous asking for their (1) total number of necropsies on those clinically diagnosed tuberculosis; (2) number of these non-tuberculous, and (3) pathologic diagnoses in the latter cases. Eight institutions[1] were good enough to supply these data, which are presented in Table 2.

TABLE 2.—DATA FROM OTHER INSTITUTIONS

Institution Number	Total No. Necropsies	Non-Tuberculous	Percentage Non-Tuberculous
1	13	2	15.5
2	64	2	3.0
3	92	11	12.0
4	12	1	8.3
5	45	5	11.0
6	100	14	14.0
7	12	3	25.0
8	15	0	....
Totals	353	38	10.8

Of the 353 necropsies heard from, thirty-eight, or 10.8 per cent., were non-tuberculous. The experience, therefore, is not a local one. The distribution is not the same as our own cases, however, for the sequelae of pneumonia do not seem to have been a very prominent disconcerting factor, whereas the cardiorenal diseases have given the most trouble in the experience of these other institutions.

TABLE 3.—CORRELATION OF ANATOMIC DIAGNOSES IN THE NON-TUBERCULOUS NECROPSIES OF OTHER INSTITUTIONS

Anatomic Diagnosis	No.	Percentage of Non-Tuberculous Necropsies	Percentage of Total Necropsies
Pneumonic sequelae	3	8.0	0.8
Cardiorenal	22	58.5	6.2
Aortic aneurysm	4	10.5	1.1
Malignancy	2	5.0	0.6
Septicemia	2	5.0	0.6
Syphilis	4	10.5	1.1
Pellagra	1	2.5	0.3

It may seem radical to be sounding a warning against diagnosing tuberculosis, but it must be remembered that we are dealing here with types of cases that are confused with those in the advanced stages of tuberculosis in which it is very unlikely to be overlooked, and that we are not considering the early stages of the disease, in which the tendency is to err in the other direction, that is, fail to recognize the presence of the infection.

The responsibility of institutions of this character does not end in providing a comfortable terminus for the advanced tuberculous, or in segregating from the public these sources of infection, but it includes also a careful scrutiny of its admissions and careful routine in the consideration of the ones admitted, with the possibility of ultimate cure or relief always in mind. This involves, of course, a correct diagnosis. While erring in this direction is more desirable than sending patients with advanced tuberculosis to a general hospital, yet in justice to all patients everything should be done to bring about their proper distribution. A certain percentage of mistakes is unavoidable, but it does seem, from a pathologist's perverted point of view at least, that this should be lower than the experiences recorded above.

---

[1] The cooperation of the following institutions is gratefully acknowledged: State Infirmary, Tewksbury, Mass., John H. Nichols, M.D., superintendent; Providence City Hospital, D. L. Richardson, M.D., superintendent; the Philadelphia General Hospital, Henry Sykes, M.D., late chief resident physician; Montefiori Home, New York, Dr. Wachsmann,, medical director; Kings Park State Hospital, L. I., William Austin Macy, M.D., superintendent; Tuberculosis Hospital for the District of Columbia, W. D. Tewksbury, M.D., superintendent; J. J. Kinyoun, M.D., pathologist; White Haven Sanatorium, Pennsylvania, Alexander Armstrong, M.D., chief physician; the Tuberculosis League Hospital, Pittsburgh, W. C. White, M.D., superintendent.

It is well to bear in mind that (1) a patient showing progressive loss of weight and strength, with cough, expectoration and even hemoptysis and abnormal physical signs in the chest, is not necessarily in a hopelessly advanced stage of tuberculosis, but occasionally still amenable to treatment directed to the *real* cause of the symptom complex; (2) particular attention should be paid to excluding cardiorenal conditions and pneumonia with its sequelae, and (3) one sputum examination, either positive or negative, should not be depended on to establish a diagnosis.

Harvard Medical School.

CONTRIBUTIONS TO THE PHYSIOLOGY OF THE STOMACH

XXI. THE SUPPOSED ACTION OF THE BITTER TONICS ON THE SECRETION OF GASTRIC JUICE IN MAN AND DOG *

A. J. CARLSON,

Assisted in part of the Experiments on Dogs, by
Miss Bertha Torchiani and Mr. R. Hallock

CHICAGO

We have shown (for man and dog) that the so-called stomachics or bitter tonics acting in the stomach alone have no appreciable influence on the hunger mechanism when given in the usual therapeutic quantities.[1] If the stomachics are taken by mouth in the ordinary way, all of them inhibit gastric tonus and hunger contractions in direct proportion to the intensity and duration of stimulation of the nerve endings in the mouth. If the bitters are introduced directly into the stomach in quantities considerably in excess of the therapeutic dose they all cause inhibition of the gastric tonus and hunger mechanism, evidently by stimulation of nerve endings in the gastric mucosa. In brief, the bitter tonics, in so far as they influence the hunger mechanism directly, cause inhibition or depression of hunger. According to Heubner and Reider,[2] large doses of bitters also retard the emptying of the stomach (dog). This must be due to a direct depression of the gastric movements of digestion, or to a retardation of the digestion process itself.

The present series of experiments deal with the question whether these tonics are capable of influencing the secretion of gastric juice, and in that way act favorably on gastric digestion. The literature on this subject is both considerable and conflicting. It seems pretty well established that the bitters have no action on the pepsin-hydrochloric acid digestion itself, except possibly in way of slight retardation.[3] This slight retarding action is of no practical significance, especially when the bitters are taken twenty or thirty minutes before the meal, or even just before the meal, because of the great dilution with gastric juice, saliva and the fluids of the food. The literature also points to the conclusion that by themselves the bitter tonics are incapable of causing secretion of gastric juice either by acting in the mouth or in the stomach. Pawlow[4] noted in dogs that the bitters acting in the mouth cause a copious flow of saliva, but leave the gastric gland perfectly quiescent; and not even when introduced into the stomach do they cause secretion of gastric juice.

Some observers (Reichmann,[5] Scheffer[6] and others) have reported that as long as the bitters remain in the stomach they depress or diminish the secretion of gastric juice, and this led to giving the bitters from ten to thirty minutes before the meals.

Do the bitter tonics augment the secretion of gastric juice indirectly by increasing the excitability of the nerve endings of taste in the mouth, and possibly the nerves of appetite sense in the stomach? This is the view emphasized by Pawlow,[7] but he does not adduce any experiments in its support. The work of Borissow[8] seems to confirm it, however. Borissow reports twelve sham feeding tests on one dog with gastric fistula and esophagotomy. Six of these tests were made after giving the dog tincture of gentian in the mouth. In both series of tests the sham feeding was continued for one minute and the gastric juice collected for two hours following the sham meal. In the case of the gentian series the sham feeding was instituted as soon as the profuse salivation induced by the bitters had ceased. Borissow obtained the results recorded in Table 1.

TABLE 1.—SHAM FEEDING TESTS OF BORISSOW

Series	Minimum c.c.	Maximum c.c.	Average c.c.
Normal or no tonic	59.3	126.5	101
Tincture of gentian	85.1	185.2	130

There was no difference in the acidity and the pepsin concentration of the gastric juice of the two series, but the average excess of gastric juice in the gentian series is striking. However, it may be questioned whether a short series of tests on one animal can be held as conclusive, especially in view of the great individual variations (over 100 per cent.) within each series.

EXPERIMENTAL PROCEDURE ON MAN

It will be recalled that Mr. V.,[9] our man with permanent gastric fistula, has the esophagus completely constricted at the level of the upper end of the sternum, so that nothing can be swallowed from the mouth and reach the stomach via the esophagus. Above the constriction the esophagus is somewhat dilated so as to hold about half a glass of liquid. These conditions serve admirably for studying the influence of the bitters on the secretion of gastric juice.

On all test days 100 c.c. of water were put into the stomach 120 and sixty minutes before the meal, so as to insure a completely empty stomach. The tonics were introduced into the stomach via the fistula between fifteen and thirty minutes before the meal time. In the series of tests with the tonics in the mouth, these were put into the mouth and swallowed into the esophageal pouch ten minutes before the meal. They usually had to be expectorated before the meal actually began, because of the salivation induced by them.

In all three series of tests the gastric juice was collected during the first twenty minutes Mr. V. was chewing his food in the usual way preparatory to putting it into the stomach by means of a syringe. We are therefore dealing with the *appetite gastric secretion only*.

The stomach was invariably emptied just before Mr. V. started to eat, and record kept of the quantity, acidity and pepsin strength of this juice found in the empty stomach, as it was thought that the quantity and quality of this juice might serve to indicate the physiologic condition of the gastric glands, irrespective of the condition of the appetite.

The experiments were made during the months April to November, 1914. The tests with the tonics were interspersed with controls without the tonics all the way, so as to eliminate as far as possible the errors from variations in nutrition, appetite, etc., associated with variations in climate and in bodily activity.

It was aimed to make these tests a mere incident in Mr. V.'s daily routine. For that reason no special dietary standard was fixed. The ingredients of the noonday meal Mr. V. selected for himself at a nearby cafeteria. He naturally selected what appeared to him most palatable from day to day. The evening meal was taken in the same boarding house throughout the experimental period. Mr. V. states that the boarding house meals are very much the same from week to week, and less palatable than the noonday meal.

The tonics used (in therapeutic doses) were tinctures of gentian, quassia, calumba, humulus and condurango, and elixir of quinin, strychnin and iron. Most of the tests were made with the gentian tincture and with the elixir.

In order to exclude all possible psychic factors, Mr. V. was not told of the purpose of the experiments. He went about his daily work, taking his usual food at the usual time, while now and then a tonic was given and the appetitie secretion measured. I think it may be safely concluded that such psychic factors as faith in the potency of or hope of improvement from the drugs were entirely eliminated. Nor was the taking of any of these tonics by the mouth disagreeable or loathsome, so as to induce psychic depression.

RESULTS ON MAN

Fifty tests were made with bitters in the mouth and thirty-five with bitters in the stomach, with fifty-one control tests. These are summarized in Tables 2 and 3. The lunch and supper series are tabulated separately, because the appetite gastric secretion was uniformly less at the evening meal. This is probably due to less palatable food at the evening meal (absence of variety in the food, inferior cooking).

Examination of Tables 2 and 3 shows that the bitter tonics acting either in the stomach or in the mouth are practically without influence on the quantity of the appetite psychic secretion. There is a suggestion of an increased secretion with the bitters in the mouth for the noon meal series, but this is counterbalanced by a slightly lower figure for the evening meal. Table 3 indicates that the average physiologic condition of the gastric glands is practically the same in all the series.

As Mr. V. is a young man in good health, the question naturally arises whether the sensory nerves for the appetite sense (in mouth and stomach) are not normally in a state of maximum excitability, so that no further increase in excitability by bitter tonics is possible. This objection seems to be met by the lower secretion at the evening meal. Here is a condition in which *less palatable food should have been rendered more palatable by contrast with the bitter tonic*, or by actual increase in the excitability of the gustatory nerves. The results indicate no improvement by contrast. If the bitters in the mouth augmented the excitability of the taste nerves at the evening meal, this evidently caused an already unpalatable food to taste still more unpalatable, and hence the diminished appetite secretion.

These bitters in mouth or stomach produced no change in the acidity and in the pepsin concentration of the appetite gastric juice.

TABLE 2.—GASTRIC JUICE SECRETED BY MR. V. DURING THE FIRST TWENTY MINUTES OF CHEWING FOOD

Meal	Tonics	No. of Experiments	Gastric Juice in c.c. Lowest	Highest	Average
Lunch, 12-1 p. m.	No tonics	31	35	95	58.0
	Tonics in mouth..	30	30	93	61.0
	Tonics in stomach	20	40	85	58.2
Supper, 6-7 p. m.	No tonics	20	20	50	36.0
	Tonics in mouth..	20	20	48	33.0
	Tonics in stomach	15	18	47	30.1

TABLE 3.—GASTRIC JUICE IN EMPTY STOMACH OF MR. V. BEFORE EATING, IN THE EXPERIMENTS OF TABLE 1.

Meal	Normal, No Tonics	Tonics in Mouth	Tonics in Stomach
Lunch	18.3	18.4	19.2
Supper	16.6	15.0	17.2

EXPERIMENTAL PROCEDURE ON DOGS

The work was done on five dogs provided with an accessory stomach pouch according to the Heidenhain-Pawlow method. Care was taken to interfere as little as possible with the distribution of the vagi to the stomach pouch.

The tonics were introduced into the main stomach by means of a stomach-tube so as not to come in contact with the nerve endings in the mouth or esophagus. They were introduced into the stomach pouch directly with a pipet. When introduced into the mouth the bitters were soaked up in a small wad of cotton and the dog was compelled to chew on this for one minute. The tests were made twenty-four hours after the previous meal, and each dog was fed a fixed quantity of boiled lean meat. The gastric juice was collected for two hours after the beginning of the feeding.

The tonics were put into the main and accessory stomachs from twenty to thirty minutes before feeding, and into the mouth ten minutes before feeding. The size of the dogs varied from 5 to 8 kg. The quantity of tonics put into the stomach varied from 1.5 to 2 c.c.

The following bitters were used: tincture of gentian quassia and condurango and elixir of iron, quinin and strychnin.

RESULTS ON DOGS

Our results on the five dogs are summarized in Table 4. The data in this table permit only one conclusion, namely, that *these bitters acting in the mouth or in the stomach have no effect on the secretion of gastric juice in the dog*. The slight increase that appears in the case of Dog 5 would probably have been counterbalanced if a larger series of tests had been made. The tonics did not produce any changes in the acidity and pepsin concentration.

TABLE 4.—RESULTS ON DOGS*

Dog	Tonics	No. of Experiments	Gastric Juice in c.c. Lowest	Gastric Juice in c.c. Highest	Gastric Juice in c.c. Average
Dog 1	No tonics	17	10	33	19.0
	Tonics in mouth	15	13	29	18.4
	Tonics in main stomach	15	10	26	18.6
Dog 2	No tonics	17	3	9	5.1
	Tonics in mouth	10	3	8	4.9
	Tonics in main stomach	10	2	7	4.8
Dog 3	No tonics	15	4	10	7.0
	Tonics in mouth	10	5	10	7.2
	Tonics in main stomach	10	3	8	6.8
Dog 4	No tonics	6	6	9	8.4
	Tonics in main stomach	6	5	11	8.0
Dog 5	No tonics	10	8	16	12.2
	Tonics in main stomach	9	7	17	14.0
	Tonics in small stomach	8	7	16	14.1

* Dogs with accessory stomachs prepared according to the Heidenhain-Pawlow method. Record of the secretion of gastric juice for the first two hours following a standard meal of lean meat. The variation in the average quantity of gastric juice secreted by the different dogs is due mainly to difference in size of the accessory stomachs.

COMMENT ON THE RESULTS

The possible value of these and other stomachics, especially in digestive disorders, might be investigated by other methods, such as the determination of the actual quantity of food consumed, the time required for completion of gastric digestion, etc., with and without the tonics. And the final verdict cannot be given until all possible tests have been applied. But as regards any favorable action of these stomachics on the gastric secretory mechanism in man and dog, our results go to show that it is nil, at least when all purely psychic factors are eliminated.

The use of bitters as medicine goes back so far that there is no authentic record of its beginning, and the number of different kinds of bitters advocated from time to time as useful is a large one. They are of so varied chemical composition that the only thing they have in common is the bitter taste. Of course, in this discussion, we do not include such substances as quinin or strychnin, or the bitters with alcohol as the main constituent, as these substances have distinct physiologic actions not directly related to appetite, after absorption into the blood.

The bitter tonics are still common "home remedies" and favorite "drug-counter prescriptions." They are often prescribed as a matter of routine and sometimes ordered because the physician actually believes they produce good results. Is this belief well founded? These tonics are given to convalescents who would continue to improve, tonic or no tonic, and the tonic, not the recuperative power of the patient, gets the credit. For many ailments the physician prescribes a more hygienic living and a tonic. The patient's health improves and both physician and patient think the tonic did it.

But even if the bitters have no direct action on gastric secretion and digestion, and no appreciable indirect action on the secretion of gastric juice, may they not be valuable aids in expelling worry and in implanting hope and good cheer in the mind of the patient? May they not be an efficient handmaid to psychotherapy? According to Cushny[10] that is their main, if not their only value. There is no question that the bitter tonics connect up with the popular belief that the potency of a medicine is directly related to its strong (or bad) taste. And the readiness with which these tonics are dispensed by the physician nourishes the popular superstition that there is, or must be, a specific drug remedy for every ailment, a superstition that constitutes the open sesame of the medical quack and the patent medicine vender.

The stimulation of certain nerve endings in the mouth and in the normal gastric mucosa unquestionably contributes to the complex sensation of appetite,[11] and these nerves are stimulated by condiments and flavors of food. Apart from this, the physiologic way of augmenting hunger and appetite is moderation in the food intake or increasing the utilization of the food in the body by work and cold.[12] If these measures do not improve appetite and hunger, the chances are that the digestive tract is not in a condition to take care of the amount of food demanded by the stronger hunger and appetite sensations.

To be sure, in therapeutic doses these tonics may be harmless, except in so far as their use contributes to the drug habit in emphasizing the "take something" instead of the "do something."

THE ETIOLOGY AND PATHOLOGY OF BONE AND JOINT TUBERCULOSIS *

JOHN FRASER, M.D., M.Ch., F.R.C.S.E.
Assistant Surgeon, Royal Hospital for Sick Children
EDINBURGH, SCOTLAND

My first duty is the pleasant one of thanking you for your kindness in asking me to read this paper. I very much appreciate the honor you have shown me.

I have chosen "The Etiology and Pathology of Bone and Joint Tuberculosis" as the subject of my paper, because in Edinburgh we have lately been doing some work in this connection which may interest you.

It will aid later in understanding if I explain now that my remarks may be summarized under two headings: etiology and pathology.

ETIOLOGY

The essential etiologic factor is, of course, the lodgment of the tubercle bacillus; but this primary factor is intimately related with two secondary considerations which are of great importance; and these two considerations are: (1) the type of bacillus which causes the disease, and (2) the route by which the organism reaches the site of its development.

1. *The Type of Bacillus.*—It is universally agreed that by certain peculiarities various subclasses or species of tubercle bacilli may be recognized. There are the important divisions of the typus humanus and the typus bovinus, and pathologically the less important avian and piscine varieties.

From the point of view of pathology, and more especially from the clinical aspect, the human and bovine types of tubercle bacilli are those which more closely claim one's attention. Why should there be such anxiety to find out the relative part played by the human and bovine bacilli? The reason is obvious. The routes by which the bovine bacillus attacks the human body may be limited to a single one, namely, the alimentary tract. The alimentary tract is infected by the ingestion of bovine tubercle bacilli in milk; and therefore, after an attempt at a logical sequence, it is the question of milk infection which is at the bottom of all this seeking after knowledge with regard to the type of bacillus in bone and joint tuberculosis.

* Read before the Section on Orthopedic Surgery at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

This paper would be incomplete if I did not touch on the methods by which it is possible to differentiate between human and bovine bacilli. There are five possible tests recognized.

A. The rapidity of growth on mediums. Tubercle bacilli may be grown on various mediums, and one of the most suitable is inspissated egg (Dorset's medium). If comparison cultures are made of human and bovine organisms, it will be found that at the end of a common period the human bacillus will have grown more luxuriantly and more profusely than the bovine. This, however, cannot be considered by any means an absolute test; there is a large border line on which the organism grows neither profusely nor scantily.

B. The second possible test is based on another peculiarity in growth. It has been found that glycerin exerts a depressing effect on the growth of the bovine bacillus while it tends to stimulate the development of the human bacillus. Accordingly a medium is made consisting of egg and glycerin, and on it the doubtful bacillus is grown.

A profuse growth means a human bacillus; the organism which grows scantily, perhaps not at all, is bovine. Once again, one must confess, the test is by no means an absolute one for the same reason as before—a group which is on the border line.

C. At one time it was thought that there were great possibilities in distinguishing between groups of tubercle bacilli by their morphologic characters. Long bacilli were considered to be human; the short, squat bacillus suggested the bovine organism.

For all practical purposes the test is useless. There is one morphologic characteristic, however, to which one must attach some degree of distinctive power. It is the characteristic of nodular staining. Certain bacilli when stained with a modification of Gram's stain (Much's method) show dark nodules which look like spores, and what one would say is, that bacilli showing nodules are almost certainly human, while all bacilli which do not show them are not necessarily bovine.

D. Theobald Smith introduced a test of which he has made considerable use in differentiating between the types. A medium is made consisting of bouillon and glycerin. The medium is of a known slight acidity, and on it a pellicle of the bacillary growth is encouraged. As the organism grows, certain changes become apparent in the acidity of the medium—the acidity may progressively increase, and this is taken to indicate that the growing bacillus is human in type. On the other hand, the acidity may diminish and the medium may actually become alkaline; such is supposed to be pathognomonic of the bovine bacillus.

E. The inoculation test. This test depends on the susceptibility of the bovine species to the infection with the bovine bacillus; it may be carried out on calves, but for economic reasons rabbits are more suitable.

A full-grown rabbit is infected intravenously or subcutaneously with a small known quantity of tubercle bacilli (0.01 mg. intravenously or 10 mg. subcutaneously). After the inoculation one of two things will happen: the rabbit may show no ill effects; its weight increases or remains constant and if it is killed, six months after the injection, the only evidence of tuberculosis will be found in the shape of a few epithelioid follicles in the lungs. The other possibility may be a very different one; the inoculation is followed by a rapid loss in weight, an increasing cachexia, and death within six weeks. Post-mortem examination shows a generalized and rapid tuberculosis. The first result is produced by a human bacillus, the second by a bovine.

By methods such as these which I have outlined, a series of cases has been examined. It has been found that a proportion amounting to 62 per cent. owe their origin to the bacillus of bovine tuberculosis. These cases have been drawn entirely from Edinburgh and its neighborhood and the results obtained give one very serious food for thought. They can mean only one thing—a milk infected to a highly dangerous degree. Since these investigations a thorough examination of the Edinburgh milk supply has been made by Dr. Miller and Dr. Mitchell. The former has found that 16 per cent. of the samples which he examined were infected with bovine tubercle bacilli. The latter has found an even higher degree of infection, namely, 20 per cent.

There is one remark I wish to make regarding the cases due to the human bacillus which amounted to 38 per cent. In every case an inquiry was instituted into the question of tuberculosis existing among the other members of the family.

It was found that in 71 per cent. of these cases there was a history of tuberculosis—usually pulmonary—existing or having existed in the family.

The practical lesson to be drawn from such a fact is the importance of isolating pulmonary tuberculosis.

2. *Routes of Infection.*—The next question to be considered is the route or routes by which the organisms reach the sites in which they later develop.

Bones and joints are rarely the situation of the primary development of tuberculosis; when they are attacked, it is secondary to some more distant infection, and the vehicle by which the infection is carried is the blood, or the lymph stream. Much controversy has been waged over the fact of whether the bone or the joint is the first to become infected, and I shall briefly tell you what experiment would appear to prove.

First and foremost, it is an undoubted fact that it is difficult and in many cases impossible to infect the cavity of a healthy bone with tubercle bacilli—the resistance of the marrow is too great, and the bacilli are almost invariably destroyed.

The second point is, that the joints are readily infected, and the infection is borne to them by the blood-stream. The anastomosis of the circus vasculosus in the fringes of the synovial membrane is more exactly the situation in which the disease begins.

Now clinically an osseous tuberculosis does occur and one naturally asks how one is to reconcile such an occurrence with the two statements just made. The explanation is as follows: While tubercle bacilli cannot develop in a healthy marrow, yet if the marrow is altered, the disease may arise therein. The change in the marrow is of the nature of a gelatinous degeneration—a disappearance of the true marrow-cells, and a proliferation of the fibromyxomatous groundwork.

In a marrow so altered tuberculous disease readily develops.

What causes this marrow change? It is partly the result of a vascular degeneration—an endarteritis and thickening of the vessel-wall with a resulting interference with nutrition—and partly the result of a tuberculous toxemia.

Two groups of vessels may be affected: the main nutrient vessel entering the center of the shaft, or the metaphyseal vessels passing into the bone near the epiphyseal cartilage.

The thickening of the vessels is the result of the tuberculous toxemia—the circulation of the tuberculous toxin. The thickening of the nutrient artery may be secondary to tubercle in various parts of the body; the thickening of the metaphyseal vessels is most usually the result of a focus of tuberculosis in the neighboring synovial membrane.

Therefore, what one knows experimentally regarding the etiology of tuberculosis of bones and joints may be summed up as follows: Synovial tuberculosis is readily produced, and the synovial membrane is infected by the blood-stream. Healthy bone cannot easily be infected with tuberculosis; its marrow must first undergo a gelatinous or fibromyxomatous degeneration, and such a degeneration is the result of a tuberculous toxemia and of a tuberculous endarteritis of the vessels supplying the bone, the nutrient vessels or the metaphyseal. In a bone, the marrow of which becomes so altered, tuberculous osteomyelitis develops.

PATHOLOGY

The first point to arise under the question of pathology is the exact situation of the bone in which the disease begins. I need not remind you of some of the anatomic facts: the epiphysis, the epiphyseal cartilage, the metaphysis and the diaphysis.

The disease may begin in the center of the diaphysis, as is seen, for example, in spina ventosa or tuberculous disease of the short and short long bones. On the other hand, the disease may begin at the articular ends, the metaphysis or in the epiphysis; and whether the epiphysis or the metaphysis is attacked depends on the situation of the reflection of the synovial membrane. If the reflection lies only in relation to the epiphysis, then the epiphysis is attacked, and, if it is in relation to the metaphysis, the metaphysis is the seat of the disease.

Changes Which Result from the Lodgment of the Bacilli

The probability is that the bacilli become originally deposited by an extravasation of the blood from one of the blood-vessels, the wall of which has been previously weakened by endarteritis. A slight sprain may be the trauma. In the effused blood the bacilli develop, and as in tuberculosis elsewhere the result of their growth is the formation of a small tuberculous follicle, perfect in every respect, with giant cells, epithelioid cells and lymphocytes. This is a point which it is important to emphasize. The primary lesion is a true follicle developing in the marrow.

As the follicle enlarges others appear around it, and, amalgamating, may form a mass of appreciable size—so large as to be apparent to the naked eye as a tiny white spot in the center of the marrow.

Coincident with the development of the follicle, changes appear in the center of the follicle and at its periphery. The central change is one of the caseation; the peripheral change is an attempt at fibrosis and localization of the follicle. If the central change is marked and the peripheral one inconsequent, the caseating disease extends rapidly throughout the marrow, and the type of disease known as "infiltrating tuberculosis" results.

If, on the other hand, the peripheral change is more evident, the disease remains localized, as an "encysted tuberculosis."

Independent of the growth of the tuberculous follicle, however, there are coincident changes apparent in the various constituents which comprise the bone, and it is from these changes that many of the clinical appearances gain their characteristic features. The structures which show changes are the bone-marrow, the bone lamellae, the periosteum and the blood-vessels.

1. *Marrow Changes.*—The changes in the marrow are twofold: an early or cellular, and a later or fibrous. The first is an actively antagonistic one, the second is more limiting in its intention.

Cellular changes: The grayness of the original follicle is always relieved by a setting of red, and such coloring is the evidence of the active changes in the marrow around.

Microscopically it is a neutrophil leukoblastic reaction, at first of immature cells, but later of fully developed polymorphonuclear neutrophils.

The cells are possessed of high phagocytic powers; they contain quantities of altered blood-pigment, and their action must frequently lead to destruction of the attacking bacilli.

This, which one may term the acute reactionary stage, lasts for about 120 hours from the date of the original infection. The character of the cells then begins to change, the polymorphonuclears diminish in number, and are replaced by two varieties of cells—a small lymphocyte and a type of immature lymphocyte or large mononuclear cell. The production of these cells is of course very suggestive of the development of tuberculosis. The connective-tissue cells remain constant, the fat cells appear to be diminished, but the diminution is more apparent than real. These changes in their sequence are most intense in the neighborhood of the diseased focus and they extend in a diminishing degree throughout the surrounding tissues. The cellular reaction of the marrow continues as long as the disease is increasing in extent, as long, in fact, as active phagocytosis is necessary. When the growth of the disease becomes arrested the cellular reaction disappears, and the marrow passes into the series of changes which end in fibrosis.

Fibrous Changes: The conversion of the marrow into fibrous tissue is a gradual process which extends over some considerable time. The change is inaugurated by a disappearance of the specialized cells (lymphocytes) with a corresponding increase in evidence of the fat cells, and the appearance among the latter of young connective tissue. This connective tissue develops from two sources: (*a*) from the connective-tissue corpuscles which lie scattered among the fat cells, and (*b*) from the connective-tissue fibrils which exist in the perivascular tissues.

The formation of connective tissue between the fat cells of the marrow gives rise to a curious mosaic-like appearance. The fat cells diminish in size and tend to atrophy, and sometimes the fat becomes broken up into an amorphous collection of analytic products. When the connective tissue is derived from a perivascular source, the vessel acquires a thickened appearance, but there is no endovascular change. The further history of the connective tissue is one of increasing density; the fibrillae tend to lie closer together and to become more compact. The degree of density is greatest in the immediate neighborhood of the diseased focus. Fibrosed marrow is yellowish-white and of a remarkably firm consistency. These marrow changes are the result of specific demands. The primary infection is that of an irritant, and as such it calls forth a simple leukoblastic reaction. With the development of the lesion the specific action of the tuberculous tissue becomes evident, and the result is the production of cells specially antagonistic to tubercle, namely, the lymphocytes. When the antagonistic attitude is no longer demanded, the marrow undergoes a sclerosing change in order to limit and encapsulate the focus.

2. *Lamellar Changes.*—When tuberculosis develops in a bone, the surrounding lamellae undergo distinctive changes. These changes are of two possible varieties, rarefaction of the lamellae—osteoporosis—and thickening of the lamellae—osteosclerosis. In an individual lesion only one type of change may occur, but it is more usual to find the two types occurring together.

Osteoporosis: Rarefaction of the lamellae is brought about by true absorption of the bone, or by a variety of metamorphosis. Osteoclasts are the medium when absorption is the end in view. They appear beside the lamellae, and as a result of their action excavations appear which are known as Howship's lacunae. By continuation of the process large areas of bone are removed, and individual lamellae in process of removal acquire a typical worm-eaten appearance. This is the more rapid mode of rarefaction; it is best seen in those instances in which a considerable portion of bone must be quickly removed and replaced by a specialized fibrocellular marrow.

The metaplastic is the second method of rarefaction, and of the two it is the more common. A lamella is built up of a dense connective tissue, impregnated with lime salts. In the process of metaplasia the lime salts disappear and the fibrous elements remain. At first the position of the original lamella is evidenced by the unusual density of the fibrous tissue, but it quickly becomes imperceptibly merged in the surrounding tissues.

While one has drawn an absolute distinction between these two methods of rarefaction, it must be remembered that the two may and do occur synchronously in the same specimen.

Osteosclerosis: Osteoblasts derived from the connective tissue cells are the factors by which the lamellae increase in thickness. They arrange themselves along the surface of the latter, and deposit successive layers of dense new bone. This new bone possesses certain peculiarities which at once distinguish it from the old: it contains a greater number of bone corpuscles, it stains a lighter color, and the junction line between the old bone and the new is sharp and distinct, with an edge which is often irregular. The process of osteosclerosis is indicative of the more chronic types of bone disease; its objective is a limiting one, but a more passive limitation than that of fibrous marrow, for example.

3. *Periosteal Changes.*—It is recognized clinically that a subperiosteal thickening is one of the earliest features of tuberculous disease of the underlying bone. Such a subperiosteal thickening is the result of a deposit of periosteal bone, and the activity of the periosteum depends on an increased vascularity secondary to the underlying disease. The deposited bone is one of two kinds, porous bone or dense bone, and with each variety the method of formation differs.

Method of Formation of Porous Bone: In the deeper layers of the periosteum, in addition to numerous osteoblasts, there are always to be found a number of osteoclasts. The function of these is normally in abeyance, but by their activity they carry out a preliminary which is essential to the later stages of new periosteal bone formation. The osteoclasts eat out a series of lacunae along the shaft of the bone until the usually smooth surface becomes rough and irregular. Their activity is short-lived, and the completion of the surface excavation is the signal for the cessation of their labors. As soon as the osteoclasts cease their activities, the osteoblasts, which meantime have been proliferating in the deeper parts of the periosteum, suddenly begin to functionate, and a thin layer of new bone becomes deposited on the uneven surface of the irregular shaft. The introductory excavation of the osteoclast is quite an intelligible proceeding. If the periosteal bone had been deposited on a perfectly smooth and even shaft, it would have required only a slight degree of violence to dislodge its attachment, but the preliminary roughening of the surface is sufficient to prevent the possibility of this occurring.

After the first layer of bone is deposited, a second tier is begun. At certain points conical projections of new bone appear. They extend outward as small spines and in the interspinous intervals there is a quantity of granulation tissue and one or more blood vessels. The scheme of architecture undergoes further changes when the spines become joined at their extremities, and a series of arches is formed. Successive series of arches are in this way deposited until a varying thickness of porous bone has been laid down. It is a scheme of architecture in which nature combines a maximum of strength with a minimum of weight.

Method of Formation of Dense Bone: Occasionally the new periosteal bone is compact in character. The preliminaries are similar to those in the deposit of porous bone, but in the later stages no arches are formed, the bone remaining compact throughout. This is the method of deposit which one finds occurring in the neighborhood of joints, the reason being that the amount of its deposit is never excessive; the more profuse porous bone might easily interfere with the mobility of the joint.

4. *Changes in the Blood Vessels.*—One cannot fail to be struck by the frequent occurrence of endarteritis obliterans in bone tuberculosis. The disease affects the smaller vessels and occasionally the primary divisions of the nutrient vessel. In histologic detail the changes closely resemble those which occur in syphilis, but the changes in the tunica adventitia illustrate a distinctive feature. In syphilis the external coat is infiltrated and surrounded by a number of small lymphocyte cells; in the endarteritis of tuberculosis no such cells are to be found; instead there is a development of perivascular connective tissue. The condition arises from the corculation through the vessels of a tuberculous toxin. The change has far-reaching results; the narrowing of the vessel lumen gives rise to considerable disturbance in nutrition, and many of the fibroid changes in the marrow are sequelae to it. Further, the disease of the vessel wall has an effect on the local development of tuberculosis. Many of the cases of so-called primary tuberculous disease occurring in the metaphysis of the long bones, the short long bones, and the short bones owe their origin to an antecedent endarteritis of the larger blood vessels.

The Gross Pathologic Varieties of Osseous Tuberculosis

The previous section has been devoted to what one might term the general pathologic changes, changes which in some degree at least are common to all forms of the tuberculous lesion. Each case of tuberculosis, however, possesses some peculiarity in its general features which justifies its classification under a special type of the disease. Therefore one may classify four different varieties: (1) the encysted tuberculous lesion; (2) the infiltrating tuberculous lesion; (3) the atrophic tuberculous lesion, and (4) the hypertrophic tuberculous lesion.

1. *The Encysted Tuberculous Lesion.*—When the disease focus, after enlarging to a certain extent, becomes shut off and localized, it is termed an encysted tuberculosis. The encysted tubercle is the commonest variety. It is also the most chronic, and its chronicity is evidenced in every step of its formation.

Macroscopic Appearances: The fully developed lesion varies considerably in size: A common gage is from a pea to a walnut. For descriptive purposes it may be considered in a series of zones. The center is occupied by an area of translucent jelly-like material, through which are scattered a number of opaque gray points, rather resembling putty in appearance. When the lesion is of some age the individual opaque spots amalgamate and form a central caseous patch, which is surrounded by a thin shell of the original jelly-like material. Passing to the periphery, there is a band of pinkish-white running round the translucent zone and sharply defined from it. The circumference of this zone merges imperceptibly with the surrounding marrow, which at the line of junction is somewhat more congested than usual. When the disease is of considerable age, the central portion becomes converted into a collection of semi-fluid débris, giving the part a cystic appearance.

Microscopic Appearances: The disease begins as a follicle of the loose reticular type. It enlarges until it can be appreciated by the naked eye as a gray opaque pin-point in a setting of red marrow. There is a ground work of branching connective-tissue cells, and the interspaces are filled with epithelioids and mononuclears: giant cells are usually present.

The impression afforded is one of a chronic and slowly developing tubercle. As the disease develops in the marrow, it comes to surround and enclose a number of bone lamellae, and the latter undergo rarefaction and absorption by means of osteoclasts, the slow development of the follicle usually affording sufficient time for the absorption to become complete. If the absorption of the lamellae should not be complete, the particles which are left, being isolated by the diseased tissue, undergo necrosis and become converted into small sequestra, commonly known under the term "bone sand." In the central clear deposit, areas of caseation appear, and they may coalesce into a patch of considerable size. Around the tuberculous tissue there is a limiting band of connective tissue. It is the pink, limiting band which has been noted in the macroscopic appearances, and it is developed from the connective tissue elements of the surrounding marrow. The changes in the surrounding marrow are not extensive; close to the disease the connective-tissue cells proliferate, and the marrow acquires a loose fibromyxomatous character.

One would summarize the sequence of events as follows: A deposit of reticulated tubercle appears in the center of the marrow, and it increases in amount, the bone lamellae being absorbed, until it forms an appreciable gelatinous-looking patch. Caseation appears in the center of the patch, and the lesion is localized by the formation around its periphery of a pale pink band of loose connective tissue.

2. *The Infiltrating Tuberculous Lesion.*—Nélaton described an infiltrating type of bone tuberculosis in 1836, and it was probably the first variety to be distinctly classified. It essentially represents the acute form of the disease.

Macroscopic Appearances: The naked-eye appearances are best appreciated in a lesion of some considerable size. As in the encysted disease, there is a natural division into a series of zones. The center is occupied by a pale-yellow area, yielding and crumbling when touched: it is the rarefied bone framework, the interstices being filled with caseous débris.

Nélaton described it accurately when he called it *l'infiltration puriforme.* Extending around the central patch there is a zone of gray semitransparent tissue (*l'infiltration grise*), which merges almost imperceptibly into both the central and peripheral tissues. The appearance is afforded by the infiltration between the lamellae of tuberculous granulation tissue which has not yet passed on to caseation. Around the gray zone the marrow is more congested than usual. It constitutes the third or red zone (*l'infiltration lie de vin*). At the line of junction of the gray and the red the latter is sometimes modified to form a paler pinkish band.

Microscopic Appearances: In its earliest stages the infiltration type of disease begins as a deposit in the marrow of a number of groups of epithelioid cells. These coalesce until an appreciable area is occupied by the diseased tissue. The naked-eye appearance is that of a gray, semitransparent tissue filling the interlamellar spaces. Its exact structure is difficult to elucidate. It is composed of densely packed masses of mononuclear and epithelioid cells. Intercellular connective tissue is at a minimum and here and there are branching connective-tissue corpuscles. There is an early arrest of the vascular supply, and to this change one must attach considerable importance; it hastens the process of caseation and in all probability it greatly depreciates any attempt at resistance in the surrounding tissues. Areas of caseation appear in the center of this semitransparent tissue, at first isolated but later coalescing, and it is this caseous change which gives the characteristic yellow appearance to the central part of the lesion. As the disease develops, numbers of the bone lamellae become surrounded. When this occurs an effort is made to remove each individual lamella by means of osteoclasts, and in this the process of rarefaction consists. In an infiltrating disease all active changes are arrested long before rarefaction becomes complete, the blood-flow ceases, perhaps the toxicity of the bacillus is great; at any rate the process of absorption is arrested, the lamella dies and constitutes a sequestrum. Scattered throughout the tuberculous tissue there may be numerous sequestra (*sequestres parcellaires*), each bearing evidence by its worm-eaten appearance of the degree of rarefaction which it has undergone.

If the infection has been specially rapid and acute, necrosis may occur before any degree of absorption has become possible, in which case a large lamellar area dies, and remains in contact with the surrounding bone, until it becomes separated by granulation tissue. Such constitutes a composite sequestrum. In the surrounding marrow there is a leukocytic reaction around the periphery of the disease, and the type of cell which constitutes the reaction is mainly the polymorphonuclear, the representation of lymphocytes and mononuclears being sparse. There is, in fact, a cellular reaction resembling that which one finds in acute infections, and it has been suggested that a mixed infection is the dominating factor in the pathology of infiltrating tuberculosis. Occasionally, the cellular reaction becomes modified, and there is an attempt at fibrous limitation of the disease. This is the explanation of the pink band, which one occasionally finds at the periphery. The periosteum becomes early activated, and forms masses of new bone. The details of the method have already been described. The essential factor is a congestion of the overlying periosteum, secondary to the central disease; the deposit may be localized or it may extend widely over the shaft of the bone.

3. *The Atrophic Tuberculous Lesion.*—The distinctive feature of this variety of tubercle is a wasting and atrophy of the bone lamellae. In some respects, it resembles the caries sicca first described by Volkmann in 1879, and later by Koenig in 1896; but, on the other hand, it has characteristics which associate it with the caries carnosa of Koenig and the *tuberculose charneu* of Mauclaire. It is more correct to consider caries carnosa and caries sicca as the same type of disease in different stages of its development, and confusion is avoided if both terms are combined in the single descriptive title of atrophic tubercle. The reason for this will be more obvious when the lesion has been fully described.

Macroscopic Appearances: The situation of the disease is typical in so far as it attacks the metaphyseal end of a long bone. The affected bone is uniformly and diffusely enlarged. It is much lighter than healthy bone, and its surface yields to the application of a moderate degree of pressure with a curious crinkling sensation. The periosteum undergoes a moderate degree of activity, and a thin sheath of new periosteal bone is deposited. On cross-section of the bone, after the outer shell is divided, the interior is found to be occupied with a soft granulation tissue in which atrophied lamellae are scattered. The granulation tissue is of a flesh color, and throughout its substance there are numerous spaces, producing a spongy appearance. The changes may extend to the articular cartilage, but the latter is never invaded.

Microscopic Appearances—Changes in the Marrow: The earlier changes appear in the marrow, and in their development they are slow and insidious. Gradually the connective-tissue elements increase at the expense of the fatty tissue, and the marrow becomes transformed into a variety of granulation tissue. The granulation tissue is largely composed of connective-tissue cells of a myxomatous type, and the vascularity of the part is considerable. There are numbers of mononuclear cells and osteoclasts, and there is a tendency for the parts to become cystic. Scattered throughout the bone there are tuberculous follicles, but their numbers are few, and in structure they are, almost without exception, reticulated. As the disease progresses there is an ever-increasing tendency for the granulation tissue to become converted into fibrous tissue.

Changes in the Lamellae: With the replacement of the marrow by granulation tissue, the bone lamellae undergo a rapid absorption. It begins in the center of the shaft, and it is the result of the activity of osteoclasts. The absorption extends to the compact bone of the shaft, the lacunae are increased in size, and the whole appearance is one of extreme porosity.

Changes in the Periosteum: With the appearance of radical changes in the center of the bone, the periosteum acquires a sudden activity; the result is the deposit of a sheath of new subperiosteal bone of the vascular cancellous type. The further history of the periosteal bone is thoroughly distinctive of this type of lesion. When a considerable amount has been formed, the foundation from which it springs becomes undermined; that portion which lies in contact with the shaft becomes absorbed, and between the new bone and the original shaft there is a ring of granulation tissue. The periosteum goes on forming new bone peripherally, but the deeper portion continues to be removed, and this is maintained until there is a considerable thickness of granulation tissue separating the new periosteal bone from the original shaft. The result is an increased but very unstable circumference.

4. *The Hypertrophic Tuberculous Lesion.*—As there is a type of bone tubercle in which an atrophy of the lamellae is the distinguishing feature, so there is a form in which a thickening of the lamellae is the predominating factor. Its occurrence is rare, and its situation is typical so far as it attacks the metaphyseal end of a long bone.

Macroscopic Appearances: There is a diffuse thickening of the bone, beginning where the diaphysis joins the epiphyseal cartilage, and extending toward the center of the shaft. The periosteum is readily detached and, in the later stages, there is a deposit of new subperiosteal bone. The weight of the part is considerably increased. When the bone is divided in transverse section, its structure is found to be unusually dense and firm. From the healthy tissue, a hyperostosis can gradually be traced, and the hyperostosis is the result of an endosteal formation. The thickening is not uniform throughout the whole diameter. In the center, there is an area from which the lamellae have been absorbed, their place being taken by a quantity of gray semidiffluent material. Embedded in the center of the soft tissue, there is usually an elongated sclerosed sequestrum.

Microscopic Appearances: Changes in the Blood Vessels: These are given the premier consideration because they are undoubtedly the first changes to appear, and probably the vascular derangement is the essential etiologic factor in the peculiarities possessed by this type of the disease. The changes appear in the larger divisions of the nutrient vessels soon after the latter break up into their primary divisions, and they take the form of a structureless effusion around the vessel, and an endarteritis in the substance of its wall. The perivascular effusion does not remain structureless, it becomes organized and converted into granulation tissue. The endarteritis in the wall progresses, and the vascular and perivascular sclerosis soon leads to an almost complete obliteration of the vessel lumen. It is a periarteritis and an endarteritis.

Changes in the Lamellae: When the thickening of the central vessels has developed, the lamellae immediately surrounding the vessel undergo an absorption and a fibrous metaplasia. These changes depend on nutritional disturbances, resulting from the thickened blood-vessel. Where the lamellae have become absorbed, the resulting space is occupied by a fibromyxomatous tissue. Outside the central area of absorption the lamellae become thickened, and the hyperostosis results from the deposit of bone by osteoblasts lining the lamellar surfaces. It is essentially an endosteal thickening, and the result is a remarkably firm dense bone.

Formation of Sequestrum: When an area in the interior of the bone has been absorbed and replaced by granulation tissue, a variety of sequestrum occurs about the center of the bone. It is the type of sequestrum Ollier called *le sequestre dur*. Its method of formation is as follows: A number of osteoblasts, assuming a sudden activity, deposit a quantity of closely arranged new bone in the center of the area from which the lamellae have been absorbed. This original deposit is not permanent. When it has reached a certain size, it becomes absorbed and is redeposited as a firmer, denser bone. This process of absorption and remodeling is repeated until the deposit is densely sclerosed. Up to this point of development, the term sequestrum is a misnomer, the tissue is not dead. Later it becomes a true sequestrum from the interference with its blood-supply. These are the appearances which one finds on cutting through the center of the diseased bone: an outer zone of hyperostosis, an elongated central sclerosed sequestrum, and an intermediate area of soft granulation tissue.

Changes in the marrow: Mention has been made of the formation of fibromyxomatous tissue in the center of the bone. Generally the marrow undergoes a fibrous degeneration. True histologic evidence of tubercle occurs in the shape of a number of follicles developing in the granulation tissue in the center of the bone.

Changes in the Periosteum: In the early stages of the disease, the periosteum shows no reaction, and the thickening is entirely endosteal in its origin. In later stages, the periosteum is activated, and deposits a thin layer of new bone around the sclerosed shaft.

ABSTRACT OF DISCUSSION

Dr. Leonard W. Ely, San Francisco: I am confronted by a tragedy! The theory, or the inference, which I have nursed so carefully for the past three or four years is in danger of sudden demise. We have all watched Mr. Fraser's remarkable work on bone and joint tuberculosis; and while some of us have not, in the past, been able to agree with him in his conclusions, I think that the evidence which he presents is staggering. He has done most careful work. His methods have probably never been approached in thoroughness; and our first impulse, when hearing his views, is, as it always is when we hear something new, to say, "Why, that cannot be so; because that does not agree with my experience." Well, if careful and scientific work does not agree with our experience, so much the worse, not for the careful work, but for our experience. These things are not to be decided forensically, with "hot air," but by hard work in the laboratory; and while I am not yet ready to accept absolute defeat, I may still say that my opinions, my conclusions, have been very decidedly shaken. It comes back to the bald statement, again, that we really do not know enough about bones and joints. We have not known enough heretofore to reach conclusions that we could depend on. We look at our slides under the microscope and see certain things; and we deduce elaborate theories from them. Another man, however, looks at our slides and deduces other very elaborate theories. Bone-marrow, when all is said and done, is almost a *terra incognita*. I hesitate to say much about this bone-marrow work now. I have always believed, of course, that the red bone-marrow was absolutely essential to the occurrence of bone tuberculosis, but in the face of Mr. Fraser's remarkable work, I would rather wait until I have some more "goods," so to speak, to deliver, before I say anything positive in that line. The battle is on and I shall try to do what I can to maintain my position.

Dr. Albert H. Freiberg, Cincinnati: I greatly admire the thoroughly scientific manner in which Mr. Fraser has proceeded with his work, and the apparently convincing facts that he has brought forward. I think that, perhaps, out of all this will come something that will be of extreme practical importance. We study the pathology of tuberculosis of the bones and joints in the living, in practice to-day, by means of the Roentgen ray; and it seems to me that we can read, in our roentgenograms, much that will be of value to us, resulting from what Mr. Fraser has shown. We have received emphasis on one fact concerning which, perhaps, Mr. Fraser will bear me out. I have been accustomed to lay great stress in the past on the fact that in the roentgenogram of tuberculosis of bones and joints, unless the cases have been in existence for a long time so that the process of repair has proceeded to a considerable extent, we practically never see new bone-formation on the surface. The process is rather one of destruction and wasting. The fact that new bone-formation is seen early in a disease I have always considered as evidence that the disease is not tuberculosis or is not uncomplicated tuberculosis. The fact that tuberculosis and syphilis can coexist, we have been accustomed to recognize for some time. I shall be much interested to hear Mr. Fraser's views on this practical point.

Dr. Fred H. Albee, New York: Confusion may arise in the microscopic study of sections in cases in which syphilis and tuberculosis exist together, or when there is a question of the differential diagnosis between tuberculosis and syphilis. It is hard to tell, microscopically, a syphilitic lesion from a tuberculous lesion, and, at times, I believe, is impossible. Dr. Freiberg has suggested an important point, that when there is bone production, one should be guarded in saying that it is a purely tuberculous bone-lesion.

Dr. Arthur Steindler, Des Moines, Ia.: In 1900 or 1902 Dr. Friedländer, in a monograph on the subject, established three distinct forms of diaphyseal tuberculosis. His investigation was a protest against the theory of the exclusively epiphyseal origin of bone tuberculosis then in vogue; in studies on this subject which we carried on later but did not conclude, we tried, in the first place, to secure earlier diagnosis of diaphyseal tuberculosis in the roentgenogram, and secondly, for early operation in order to reach tuberculous foci in ample time before penetration in the joint. Friedländer's first type was the solitary metaphyseal focus identical with the epiphyseal focus on the other side of the epiphyseal line; the second, the infiltrating form from the medullary cavity through the entire thickness of the bone; the third, the periosteal form, which showed in the roentgenogram several concentric layers of periosteal bone separated by layers of granulation tissue. This classification we used in making subdiagnoses of diaphyseal tuberculosis. In many cases solitary foci could be diagnosed and reached before penetration into the epiphyseal line.

Dr. J. D. Griffith, Kansas City, Mo.: If there is a chance of eliminating the bovine form of tuberculosis from our list of infections and getting rid of it, we shall add immensely to the longevity of our fellow-men. How does Mr. Fraser account for tuberculous infection in man without any seeming interference with the return circulation? If I understood him correctly, in his experience, he has only obtained infec-infection after interfering with the return circulation.

Mr. John Fraser, Edinburgh, Scotland: Answering Dr. Freiberg's question concerning the value of the Roentgen ray in diagnosing pathologic changes in the bones and joints, I believe that, on roentgenoscopy, one is almost certain to find the details of the pathologic changes that we find microscopically and macroscopically. We can actually see, in a roentgenogram, an endarteritis of the blood-vessel. It shows distinctly in illuminated plates, and I think that we can see the pathologic changes occurring. In this way one is frequently guided to the correct diagnosis. Dr. Albee spoke of the difficulty of differentiating between tuberculosis and syphilis. I have shown in every case, on making an injection of tuberculous material into an animal, that the animal never failed to develop tuberculosis. Among those cases which I call the hypertrophic, we found cases of inflammatory reaction, as well as the development of tubercle; and we believe that these are cases of mixed infection. Dr. Fassett spoke concerning the rarity of the occurrence of tuberculosis in the shaft, as a frequent occurrence in the epiphysis; and he mentioned the work of Dr. Noyes of Edinburgh, who thinks that it is entirely metaphyseal or epiphyseal. He does not believe that it occurs in the shaft. Yet it certainly does occur in the shaft. He does not say, however, that it is rare in the epiphysis. That is the most common situation by far. He agrees that it occurs there. Dr. Steindler spoke of the work of Friedländer on diaphyseal tubercle, and his classification, including a purely periosteal form. If you search you will find in every case a central focus. Tubercle cannot occur primarily in the periosteum. It used to be thought that it occurred in the periosteum of the rib, but osteomyelitis occurs in every such rib. Dr. Griffith spoke of the importance of eliminating bovine tuberculosis. That is the most important part of the work. If we can eliminate that we shall have accomplished a great deal. Our system of milk inspection in Edinburgh, at present, is shocking beyond words; but we hope to have this corrected. Dr. Griffith also asked how I could explain the way in which, by retarding the blood-stream, we can localize tubercle, and asked how I could account for tuberculous infection without any interference with the return circulation. I would ask him how he knows that retardation of the blood-stream does not occur in such cases. The tubercle is always secondary to some focus in the body; and with this primary focus you get a thickening of the vessels, which produces a certain amount of retardation of the blood-stream over the entire body.

RECURRENT SPONDYLOLISTHESIS, WITH PARALYSIS; BONE-SPLINT TRANSPLANTATION *

EDWIN W. RYERSON, M.D.
CHICAGO

The fifth lumbar vertebra is subject to many abnormalities of development which may cause mechanical trouble. The most frequent anomaly is probably in the shape or size of the transverse processes. This will not be considered here.

Next in frequency is a variation in the articular processes, which may vary in size, in shape, or in direction. If the articulation be of the lumbar type, with the long axis of the joint antero-posterior, and the flat facets facing to the side, it is possible for the vertebra to slide forward on the sacrum when the spine is straight or extended, especially if the articular processes be small and the ligaments weak. If the processes be of the dorsal type, and this is by no means rare, flexion of the spine, with violence, may cause the facets to override; more easily, again, if these facets be small and the ligaments be weak.

The exhaustive work of Goldthwait[1] explained clearly the mechanism of this class of lesions, but no case of displacement of the fifth lumbar vertebra with paralysis has come under my observation until last year.

CASE REPORT

History.—In the latter part of February, 1913, a strong and healthy girl of 15 was carrying another girl in her arms, in the gymnasium, when she suddenly felt a pain in her back and fell to the floor in a faint. When she awoke there was a severe pain in the lower part of her back, but after a time, with some assistance, she was able to walk home. For a week the pain continued, though less severe, and she was able to go to school, but on the eighth day her legs grew weak and began to feel numb. A week later she was unable to walk at all. The pain radiated down the back of the thighs and legs, and for a time the family physician thought it might be due to "sciatic rheumatism." As it did not respond to salicylates, a neurologist was called in consultation.

The knee-jerks were increased, a slight ankle-clonus was present, and the condition was one of spastic paraplegia. It was thought that possibly a vertebral tuberculosis might be present, with pressure on the cord. A double Buck's extension was applied to relieve the painful flexion of the knees. In a few days the paralysis had disappeared, and the child was sent to the orthopedic department of the Chicago Policlinic to have an artificial ankylosis of the vertebrae made by the Albee method.

Examination.—On examination, however, no evidence of spinal tuberculosis could be found, and it seemed probable that the condition was due to a mechanical cause rather than to disease. An actual forward displacement of the fifth lumbar was not considered as likely as a protrusion of the intervertebral disk, although no history of a sideways bending at the time of the accident could be elicited.

Subsequent Course.—The patient was now apparently perfectly well, and after a week of observation in the hospital she was allowed to go home, in the belief that the trouble would not recur without severe exertion. She was cautioned to avoid lifting any weights and to keep quiet for some weeks. For a week at home she remained well, but the next day she stumbled over some obstacle on the floor and the paralysis recurred. The Buck's extension once more rapidly relieved the paralysis and a plaster jacket was applied, fitting very low over the hips. A few days later an attack of ptomain poisoning occurred, and the jacket was removed by the family physician on account of the distention of the abdomen. Now began a series of attacks of paralysis, averaging one every ten days, until January, 1914, when the child was confined to the bed all of the time. A small and inefficient commercial brace had been applied some time before, but it did no good.

I saw her again Feb. 6, 1914, ten months after she had passed from my observation. No paralysis existed, and the reflexes were normal. On bending her backward in bed, exaggerating the lumbar lordosis, the spinous process of the fifth lumbar vertebra could be felt to move forward abnormally far on the sacrum. This caused pain in the back and a tingling and pricking sensation in the feet. On bending the body forward, obliterating the lumbar lordosis, immediate relief was felt and the child stated that this occurred habitually on similar movements. She lies and sleeps with the spine in flexion for the sake of comfort.

Treatment.—An opinion was now given that the trouble was due to the slipping forward of the fifth vertebra as a whole, and that the best way to rectify it would be to implant a bone splint by Albee's method so as to immobilize the lower lumbar spine. Accordingly, on March 11, 1914, this operation was performed at the Policlinic. A splint was cut from the left tibia, curved slightly to fit the lumbar lordosis and the sacrum, and long enough to reach from the third lumbar process to the third sacral. The lumbar and first two sacral spinous processes were readily split, but the third sacral was merely a small projection, so a groove was cut out bodily in this region. The splint was sewed in with No. 12 braided silk sutures, boiled in mercuric chlorid solution and then in paraffin. These sutures were inserted deeply and strongly, with large needles and a heavy needle-holder, and they were tied very tightly. A layer of the lumbo-sacral fascia was sewed over the whole splint, covering both splint and silk sutures.

The girl was placed in an ordinary bed and kept recumbent for three weeks, when against orders she began to sit up when the nurse was out of the room. April 7 she went home, and April 21 began to walk about. Her back felt perfectly well and strong and she remained in excellent condition until June 4, a period of over six weeks. On this latter date something gave way in her back, causing severe pain but no paralysis. Examination June 11 showed that the upper tip of the splint had become loosened from the third lumbar spinous process. The knee-jerks were normal, there was no ankle clonus and sensation and motion were undisturbed. There was easily perceptible grating and crepitus at the tip of the splint when the back was moved, and the pain was said to be quite severe on such motion. She was advised to keep perfectly quiet for a few weeks, in the hope that union might again take place, but it will probably be necessary to reattach the end of the splint by operation, or to cut the end off to relieve the discomfort. The lumbo-sacral joint remains perfectly fixed and there will apparently be no further trouble from this source.

---

* Read before the Section on Orthopedic Surgery at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

[1] Goldthwait, J.: Boston Med. and Surg. Jour., 1911, clxiv, 365.

Note.—Aug. 7, 1914. This patient was reoperated on July 1, 1914, and the upper end of the splint firmly reattached by drilling both splint and third lumbar spinous process and tying with silk. She is now sitting up in a plaster jacket without any symptoms referable to the original difficulty. The spine seems strong and the splint is apparently firmly fixed.

122 South Michigan Avenue.

ABSTRACT OF DISCUSSION

Dr. Fred H. Albee, New York City: There has been considerable uncertainty about the result of the application of bone splints in the lumbosacral region. In my experience, the result has been as satisfactory when the graft has been placed in the posterior part of the sacrum as in other regions of the spine. Although the spinous processes there are small, as Dr. Ryerson has said, we are able by means of them, together with the splitting of the periosteum on the posterior part of the body of the sacrum and the scarifying of the bone, to get good union and a good surface for the application of grafts. I have had no trouble in getting union of the grafts in this region. So far as fixation of the fifth lumbar vertebra goes, the contrast of the results of this graft fixation with that of external fixation by means of braces or plaster jackets, is very gratifying. In fact, it is difficult to fix this region by any external means.

Dr. Charles A. Parker, Chicago: One point is of practical anatomic interest in cases in which the operation might not be successful. Fortunately, in the cases reported, it was apparently very successful. This is with regard to the development of the lower half of the fifth lumbar vertebra. The gentlemen who have described that development have gone into the matter thoroughly. The portion of the arch containing the spinous process frequently develops from an entirely different center from that of the upper half, and remains separated, except for cartilage, throughout life; so in the cadaver, the big body with the shortened arch is in one piece, and the lower half, with the lower articular surfaces, in an entirely separate piece. That is the usual variation found. It is united more or less firmly. Another variation is that the two halves of the spinous process may be quite separate. One can conceive that, in a case of that kind, when the graft was implanted into the spinous process of the fifth lumbar vertebra, there would be little control of the vertebra.

Dr. J. Torrance Rugh, Philadelphia: I want to attest the value of the bone graft in this region. In a series of twenty-six cases I have had three in which the graft has been attached to the upper two sacral vertebrae, and the results have been as good as in any of the other sections of the spine. In one of my cases, after a period of six months, when the fixation was firm and the results all that could be desired, the patient on sitting down felt something give way. Examination showed a fracture of the graft between the fourth and fifth lumbar spines. She was placed in a solid plaster jacket and kept in the supine position for nine weeks, when firm union of the graft took place, just the same as it would have taken place in the shaft of any bone. At a subsequent operation, done for the purpose of attempting to reinforce this graft opposite the point of fracture, another graft was inserted; but, through a surgical error on my part, the flap of skin became devitalized, so that the graft was exposed and ultimately came out. As this was the thirteenth operation, it naturally would be expected to fail. That was the only graft that I lost in the twenty-six cases; and I think, from the experience I have had, that the attaching of the graft to the sacral region gives as good results as in any other region. Dr. Ryerson's paper is of immense importance, as opening up a field for the treatment of that most troublesome of cases, the cases of spondylolisthesis. In older patients, past 35 or 40, when it is possible by posture or some other method to eliminate the exaggerated lordosis and replace the cast, we shall have, I think, entire control of cases which hitherto have been extremely troublesome.

Dr. J. A. Nutter, Montreal, Canada: How does Dr. Ryerson explain paraplegia from so low a lesion as slipping of the fifth lumbar vertebra? I recently had occasion to examine post mortem a man with a broken back, at the Montreal General Hospital, and found a marked traumatic spondylolisthesis, probably hastened by congenital malformation of the laminae; without, however, any narrowing of the vertebral canal at that level. This man's paralysis was probably due to a coincident injury to one of the intervertebral disks, three or four vertebrae up, causing pressure on the cauda equina. We could not, at that time, attribute any of his paralysis to the fracture of the fifth lumbar vertebra. There was no narrowing of the vertebral canal at that level, in spite of the spondylolisthesis. I should like to have some light on that subject. How can injury to the cauda equina at the level of the fifth lumbar vertebra cause paraplegia?

Dr. E. W. Ryerson, Chicago: It is quite true that it is not easy to constrict the spinal canal at the level of the fifth lumbar vertebra, but it can be done; and I can think of no other method by which this little girl's paraplegia could have been caused. I could put my finger on the fifth lumbar spinous process, and pinch it, and could then bend her backward and feel it slip so far that I am afraid to tell you just how far I felt it slip. It certainly could constrict any spinal canal that I have ever seen, and I do not think that any intervertebral disk higher up had anything to do with it. She was a sensible little girl and could locate it so accurately that, although I was at first doubtful of the cause, I had to be convinced. With regard to the attachment of the splint to the sacrum, the remarks made are pertinent; but when attachment is made there, it is not mechanically at as great advantage as when it is made to the spinous process. The immobilization must be carried out for a longer time than I carried it out in this case. I should have insisted on a longer period of immobilization. I believe that we must make every effort to prevent strains on the spine. There is a terrific leverage at the third and fourth lumbar vertebrae, and it takes a strong splint to make enough bone to gain security. As time goes on, we may make an attempt to produce ankylosis of the articular facets, rather than put in a bone splint in this locality.

Results of Infant Welfare Campaign.—During 1914 infant welfare work was carried on in twelve localities in New York. During the summer there were thirty-two different localities where such work was in operation. A comparison of the vital statistics of the two summers indicates the saving of many lives. During the four summer months of 1913 there were 4,387 deaths of infants under 1 year of age outside of New York City, while for the corresponding months of 1914 the infant deaths numbered 3,833, or an actual reduction of 554. The infant mortality, based on the ratio of deaths under 1 year of age to 1,000 living births, in 1913 was 141 for the summer months, June, July, August and September, while for the same period of 1914 it was 117. The State Bulletin of Health which presents these figures, states that two factors might influence these statistics, the better registration of births and the mild summer, but a comparison with the statistics of New York City show that these are not responsible to any extent for the great drop in infant mortality. The figures show that the infant death-rate in the city dropped twelve points in 1914 below the record of 1913, while the rate for the rest of the state dropped 23 points.

THE CAUSES OF SCOLIOSIS AND THEIR RELATION TO TREATMENT *

Z. B. ADAMS, M.D.
Surgeon to Orthopedic Out-Patient Department, Massachusetts General Hospital; Fellow in Anatomy, Harvard Medical School
BOSTON

No one biased in his belief should attempt the study of either the causes or treatment of scoliosis. We must approach the subject with an open mind. Each case is a problem in itself.

The treatment of structural lateral curvature is now advancing apace with our knowledge of other medical and surgical problems. This has been made possible by the investigations of Drs. Bradford, Lovett, Feiss and Forbes, and of late the study of the subject has been stimulated anew by the announcement of Dr. Abbott of Portland. Drs. Bradford and Lovett[1] studied the motions of the normal human spine in its various positions. They found there was no side-bending without rotation and no rotation without side-bending. They also found these motions were more free in flexion.

Lovett[2] experimented with the column of bodies and disks without their posterior segments and found it obeyed the laws of physics for flexible columns.

Feiss studied the complex problems of rotation and lateral bending, both by experiments on the living and by a mechanical model of the thorax and a model of a vertebra with its attached ribs.

Dr. A. McKenzie Forbes, of Montreal, impressed by the failures of all methods to procure the so-called forcible correction with plaster jackets, undertook a further study of the subject to explain and rectify the knowledge.

He has discovered a paradox, which is this: Given a case with right dorsal rotation, the only way to reduce this rotation is to rotate the body trunk to the right. His discovery was made by observations of a scoliotic subject with radiograms, and an exhaustive study of the work of Lovett and Feiss. This rotation is in exactly the opposite direction to that practiced by Abbott and all previous operators in attempting correction. In brief, Forbes puts his patients in a position of extreme flexion and rotation. They are then held in this position by plaster jackets with large windows.

In structural lateral curvature, we are dealing with a condition, not a disease. There are many causes of scoliosis, but they are not so multitudinous and are, in general, of a very different character from what an inspection of the literature would lead one to suppose. Bad seating at school, faulty postures, malleability of the vertebrae, osteomalacia, rachitis, infantile paralysis, empyema, numerical variations, extra and fused ribs, lateral half of a centrum missing, fused vertebrae, etc. —all have a bearing on the subject, some, but not all of them are true causes. In short, have not, many times, the contributing factors been mistaken for the true cause?

When one remembers the small seats in school for the rapidly growing child, the difficulty of getting one's knees under the desk, the curled up and side-twisted position in which we were taught to write, and yet no scoliosis developed, has not in this case the contributing factor been mistaken for the cause? We all sat curled up and sidewise when in school and while growing rapidly, yet no scoliosis developed.

Rachitis, osteomalacia and other bone softenings go into the same list. We have all seen profound rachitis without scoliosis.

Short leg, from whatever cause, and many other so-called causes are subject to the same criticism. Scoliosis occurs in some cases in which they exist, but if they are the cause, why does it not occur in all? The answer is, they may be a contributing factor, but they are not the cause.

Some years ago, Dr. Böhm[3] beautifully elaborated the theory of numerical variation, advanced by Rosenberg, to account for some of the anomalies which occur in the spine and its appendages. Possibly he has since expanded this theoretical garment to envelop spina bifida and all the rest of Nature's defects in the human frame.

Dr. Böhm stated in his paper that asymmetric sacralization might cause a lateral tilting of the top of the sacralizing vertebra and thus cause scoliosis. An inviting supposition, but it does not prove to be the cause in many cases of scoliosis.

Roentgenograms of the scoliotics at the Children's Hospital showed but few in which there was asymmetrical sacralization, and in these few, the top of the sacralizing vertebra was not tipped. At the Massachusetts General Hospital, in taking roentgenograms of subjects with indefinite pains in the back, or when renal or ureteral stone, etc., is suspected, asymmetrical sacralization in all degrees is often found but there is no scoliosis. If ever a cause it is a rare cause.

The Dwight Collection of spines in the Warren Museum further bears this out. Of the nineteen spines showing asymmetric sacralization but one has scoliosis, and that one also shows an absence of the right neural process of the first sacral segment, which is of far greater importance, so far as the cause of the scoliosis is concerned. But Dr. Böhm aroused interest in the anomalies of the spine and the effects they might produce, and for this deserves great credit.

Some three years ago in checking up the work of Dr. Böhm the conclusion was reached that so far as the cause of scoliosis is concerned, congenital defects of the articular processes were of far greater importance than asymmetric sacralization.

The weight of the trunk and upper extremities is largely borne by the flexible column of the vertebral bodies and disks, but it is also supported in a varying degree by the two more rigid posterior columns of the articular processes. Thus the support is tripedal.

With this in mind, we can all see how a missing half of a centrum, a wedge-shaped centrum, whether congenital or pathologic, or an extra osseous center on one side between the bodies, will cause lateral deviation and rotation, hence lateral curvature.

Such cases are rare; however, they form a class which show certain characteristics of their own, especially when they occur in the upper dorsal and cervical regions. The deformity usually appears early in life. They originate from defects in the embryo about the sixth week.

---

Anomalies of the sacrum, involving its neural arch or articular processes are very common. Dr. Goldthwait has already drawn the attention of orthopedic surgeons to these facts and has shown their relation to back strain.

Obstetricians realize the variations in inclination of the female pelvis, and the varying degrees of prominence of the fifth lumbar body, and Dr. Lloyd Brown has made clear the importance of these facts in the production of back strain and ptosis. In the female the average sacrovertebral angle is considerably (13 degrees) greater than in the male.

The late Professor Thomas Dwight once said, "Anomalies of the fifth lumbar vertebra are so common that we hardly know what the normal should be." This is equally true of the sacrum.

Sir William Turner, the famous English anatomist, found separation of one or both of the inferior articular processes of the fifth lumbar vertebra in 5 per cent. of all subjects. The pedicles of this vertebra occasionally fail to unite with the body; spina bifida is frequent in the lumbosacral spine.

Now realizing that the base on which the column of bodies and disks rests—namely, the facet on the upper surface of the sacrum—is not directed upward, but is distinctly inclined forward as well as upward, having a pitch of 40 degrees from the horizontal in the average female, and that this pitch varies in individuals, being often much greater than 40 degrees in women, and that the only bony obstacles to the forward coasting of the fifth lumbar body on this steeply inclined surface are the articular processes in which anomalies are so frequent, one or both being separate ossicles in 5 per cent. of all persons, is it remarkable that under such conditions, the fifth lumbar body should slip forward and hence downward on this incline? At 45 degrees of inclination a movement of one-fourth of an inch forward gives one-fourth of an inch drop.

The structures preventing this forward slipping are ligamentous, with the exception of the inferior articular processes of the fifth lumbar, above mentioned, which articulate with or hook on to the superior articular processes of the sacrum. With increase of the vertebrosacral angle comes increase of this tendency to slide forward, hence an increased strain, vertical as well as horizontal, on these four small processes. As the inclination increases, the horizontal thrust becomes greater and more vertical, that is, the two forces tend to a pure downward strain on the processes; thus in the standing position a large part of the weight is thrown on them.

The ligamentous structures which support this joint are the fibers of the intervertebral disk, which normally allows a certain excursion; the anterior common ligament which here is thin and broad; the posterior common ligament which is narrow at this level; the ileolumbar ligaments running from the transverse processes of the fourth and fifth vertebra to the crests of the ilia; the lumbosacral ligaments running from the lower edge of the transverse processes of the fifth lumbar vertebra to the top of the sacrum; the subflavous ligaments binding the lower edge of the lamina to the top edge of the sacral lamina; the interspinous and supraspinous ligaments and the articular, capsular ligaments about the articular joints. All these ligamentous structures, like other ligamentous structures of the body, are capable of being slowly stretched.

As a hypothesis let us take a patient in which one of these four articular processes is imperfect, or is detached from the centrum, or let one pair be so turned that they face outward and inward, while their fellows of the opposite side face backward and forward, or one pedicle may have failed to unite with the centrum. Under any one of these conditions, the whole support on one side would be ligamentous, while bony and ligamentous support is on the other side. The body of the fifth lumbar vertebra would sag forward and downward on one side, while it is held back on the other, hence, lateral rocking occurs with rotation of the base on which a compound mast, the spine, stands.

There will be a spondylolisthesis of one side. One side of the fifth lumbar body will swing forward about the articular process of the other side as a pivot, and due to the inclined upper surface of the sacrum will drop downward. The result of rotary motion of these two surfaces is well illustrated by a round stick sawed across at 40 degrees of inclination and the cut surfaces slightly rotated on one another.

Now suppose that the bony mass of one of these articular processes is increased in bulk, just as the transverse process of one side is increased in asymmetric sacralization. The vertebra will be pushed up by one leg of its tripedal support. We get forward and lateral tilting combined. Or if there is absence or marked undergrowth of one process, we get a backward and lateral dropping. Either is equivalent to combined side-bending and rotation, hence scoliosis. It is analogous to a camera on a level floor with one short or long leg to its tripod.

As the contributing causes, short leg, bad postures and seating, etc., have all been mistaken for the true cause. So have coexisting anomalies such as asymmetric sacralization and fused and extra ribs been mistaken for the true causes. All who have studied many roentgenograms realize the frequency with which multiple anomalies are found. In fact, it is usual to find several anomalies of varying degrees in one individual, hence the multiplicity of congenital causes recorded for scoliosis.

Anomalies of the spine may occur at any point, but they are more frequently found where a freely movable region joins one in which motion is less free, as the dorsal with the lumbar, or the lumbar with the sacral. As shown above, the joints of greatest consequence, so far as the site of the cause of scoliosis is concerned, are those in which the surfaces between the centra have a sharp downward inclination, the lumbosacral and those between the sacral segments. The sacral segments do not begin to fuse until the seventh or eighth year, and this fusion between the first two segments is often delayed. The articular processes between the sacral segments are always small and often very irregular, hence the first sacral segment may rotate on the second. This is especially found in cases in which the first sacral segment is anomalous. In rare cases it occurs between the second and third segments. The presence of an anomaly at the base of the spine even in scoliotics, does not prove that anomaly to be the cause of the scoliosis. Each case must be studied carefully, as regards the mechanical principles involved.

As the degree of forward slipping or drop depends not only on the character and magnitude of the lesion, but also on the inclination of the sacrum and extent of the consequent dorsal and lumbar anteroposterior curve, so the character of the scoliosis, caused by the same anomaly, may vary in different individuals.

The frequency of these anomalies in scoliotics is well illustrated by the clinic of the Massachusetts General Hospital. Of fifty consecutive cases in which careful roentgenoscopy has been made by Dr. Walter Dodd and Dr. Holmes, forty-four subjects showed bony defects in the sacrum or two lowest lumbar vertebrae.

Of the four patients showing no such lesions, two have infantile paralysis of five years' duration, involving the back muscles; one presents a case of syringomyelia; the others showed sharp dorsal curves with lateral deviation and rotation of the lumbar spine, but no bony anomalies in the lumbar or sacral region.

In the forty-four remaining cases above mentioned, the lesions found are as follows:

Anomaly of inferior articular processes of fourth lumbar	3 cases
Anomaly of inferior articular processes of fifth lumbar	7 cases
One large transverse process of fifth lumbar, Böhm type	2 cases
Failure of fusion, one pedicle, fifth lumbar	1 case
Overgrowth of right articular process of sacrum	1 case
Undergrowth of right articular process of sacrum	1 case
Articular process of sacrum forward	4 cases
Spina bifida first sacral segment with deformed process	9 cases
Anomalous fifth lumbar or first sacral vertebra which has rotated	12 cases
Anomalous sacrum	2 cases
Rotation of first two sacral segments on the third	1 case
Collapse of one ilium	1 case

This gives an outline of what may cause scoliosis. Mistakes in interpretation may have been made, but by the assistance of Drs. Dodd and Holmes the findings in most of them are correct.

This study brings out the value of the flexed position. In attempting correction, not only should the thoracic spine be flexed, but the lumbar spine should be flexed on the sacrum, and the sacrum flexed on the lumbar spine; for flexion separates the articular processes and helps to get the sacrum forward under the spine.

The supine position with the foot-sling helps to draw the pelvis up and forward, while gravity pulls the trunk downward.

This study also suggests that in some of these cases, and possibly in many, operation should either precede or follow correction. In the first class it should be to replace the fifth lumbar centrum to its position on the sacrum, or to remove asymmetric overgrowth of the processes, which prevent restoring the base to a position of equilibrium; and in the second class to prevent recurrence of the deformity by means of bone graft to lock the fifth centrum to the sacrum; or on the articular processes to hold the vertebra in its place.

It is evident that the lumbo-sacral region is not thought to be the only region in which is found the congenital causes of scoliosis, but it is one of the most frequent sites of the cause in those cases occurring in girls about the age of puberty. At that age the lumbosacral angle increases, that is, the downward pitch of the inclined base; the ligaments are soft, due to rapid growth; the epiphyses have not all united, especially those of the iliac crest to which the iliolumbar ligaments are attached; and the body-weight is increasing.

Careful roentgenographic study of the whole spine is indispensable before any treatment of scoliosis is undertaken. Stereoscopic roentgenograms best show the position of the fifth lumbar vertebra in relation to the surrounding structures. In early cases the radiograms should be taken with the patient standing in order to show the position of the base in lordosis and in weight-bearing.

By the procedures of Forbes and Abbott some of the deformities of the spine may be corrected, but by these methods nothing has been done to remove the cause of the scoliosis. Will the corrected spine be able to maintain its equilibrium on the unstable base, from which this spine has already fallen? Should not this point be considered before subjecting a patient to the discomfort of a forcible correction?

I wish to thank Dr. Dodd and Dr. Holmes for their interest and assistance in this work.

166 Newbury Street.

ABSTRACT OF DISCUSSION

Dr. Harry Hudson, Philadelphia: About 1908, I reported a case of congenital scoliosis with not only structural but also numerical variation. There were thirteen ribs on one side and fourteen on the other; two supernumerary vertebrae were interposed, and there was fusing of two of the ribs. This case showed me the possibilities in the way of structural changes as the cause of scoliosis; and while I have not carried out studies on this, as Dr. Adams has done, I have been careful in my roentgenoscopies since then. I now have four cases of asymmetrical sacralization of the lumbar vertebrae; one case of supernumerary half-vertebra interposed, causing an angulation of the spine; and another case of numerical changes in the ribs. I theorized considerably on this question but I did not have the energy to carry the theory out, that many cases of scoliosis must be due to some congenital malformation. That is, we cannot explain why children of ordinary good physique and musculature should suffer from so-called faulty positions, when other children of less muscular ability who have been subjected to the same conditions do not seem to have any trouble. This point should be investigated, and if we follow that line in roentgenoscopies in our cases of scoliosis we shall find more frequently, probably, minor changes in the facets and the spine. I think that they are often there and are a deciding factor in so-called cases of static scoliosis.

Dr. John Dunlop, Washington, D. C.: Dr. Adams did not seem to go very much into the question of treatment. What has he to suggest in that line?

Dr. Z. B. Adams, Boston: With regard to the question of numerical variation, I would call attention to the admirable work of Dr. Böhm, in which he followed out Dr. Rosenburg's theory of cranial or caudal progression, to explain the occurrences of the various anomalies. Certainly Böhm deserves tremendous credit. I think that although in Germany Dr. Kollicker has done some work before, yet this work of Böhm was excellent. Many of these changes, however, are not due to numerical variation; that is, to asymmetrical sacralization. It is possible to have this in all degrees without any scoliosis. Asymmetrical sacralization is found in Roentgen-ray clinics. In taking roentgenograms for suspected stone in the kidney or pain in the back we find the broad wing and no scoliosis, and this is borne out by the collection in the Warren Museum. Out of this collection there was but one that showed scoliosis, and that one shows asymmetrical sacralization with the absence of the neural arch of the first sacral segment. This allows the fifth lumbar vertebra to tilt back on one side, hence is the cause of the scoliosis. Each case must be studied by itself, with the mechanics of this portion of the spine borne carefully in mind. Concerning treatment, in the very early cases a great deal can be accomplished by teaching the children to stand in a proper position, that is, when the processes are small and show an inclination to unlock. That inclination is best shown when the roentgenogram of a child is taken in the standing position, with the lumbar spine in the position of lordosis and weight-bearing. It can be treated by exercises for the purposes of muscular development, producing a flat back and no lordosis. In the more severe cases, with a large transverse process on one side, surgical measures are demanded.

PLAGUE IN HAVANA

G. M. GUITERAS, M.D.
Surgeon, United States Public Health Service
WASHINGTON, D. C.

The first case of plague known to occur in Havana, Cuba, was discovered July 6, 1912, in the person of a Spaniard residing at No. 2 Mercaderes Street. Two additional cases occurred July 12 and 22 at Justiz and Baratillo streets, about four blocks distant from the first case. The district involved in this infection is about three blocks from the water front and in the wholesale commercial district of the city.

The infection was at first supposed to have been imported from Porto Rico, the capital of which, San Juan, was at the time plague infected. Subsequent investigation, however, by the Cuban health authorities, indicates that the infection was a direct importation from the Canary Islands, where plague was present at the time, though concealed and stubbornly denied by the Spanish authorities.

Owing to the early discovery of the disease and the thorough and excellent work of the Cuban Sanitary Department this outbreak was confined to the three cases mentioned above.

About one year and a half later, that is, Feb. 22, 1914, the first case of plague of the present outbreak was discovered in Havana at No. 1 Officios Street, which is in the block adjacent to that in which the first two cases occurred in 1912. Whether this second appearance of plague was simply a continuation of the old infection or a new importation is a moot question. The former is the more reasonable view and is supported by Dr. Juan Guiteras, Director of Health of Cuba. The case of February 22 was followed by twenty-four other cases, making a total of twenty-five within the city of Havana. The last case occurred June 22.

Two other cases were found in the neighborhood of Havana, the first at Artemisa, 45 kilometers to the southwest of the city, April 18, the second at San Jose de las Lajas, a town about 25 kilometers southeast from Havana, June 15. As the infection in both these cases was clearly traceable to Havana and they were treated in that city, these properly belong with the Havana series.

May 30 an infected rat was found in the freight station in the town of Jaruco, 37 kilometers to the eastward of Havana on the railway between that city and Matanzas. The station and surrounding structures were disinfected and there were no further developments.

June 23 a case suspicious of plague was reported from Santiago de Cuba in the eastern extremity of the island. Later it was confirmed, after inoculation tests and the exposure of guinea-pigs in the infected locality had shown positive results. Plague-infected rats were found about the same time.

It may be considered as more than probable that the spread of plague infection outside of the original focus in Havana was due to the action of a Mr. Gonzales, a wholesale provision merchant who, when one of his employees sickened with what he thought might be plague, and later was confirmed as such, concealed it, and, knowing that as soon as the case was discovered his warehouse would be quarantined and fumigated, disposed of as much of his stock as possible, sending it to various parts of the city of Havana and throughout Cuba, including the subsequently infected points, San Jose de las Lajas, Jaruco and Santiago de Cuba. He is at present being prosecuted before the courts.

It should be observed that two weeks prior to the appearance of the first case of the present outbreak in Havana, the sanitary authorities had noted some rat mortality. Anti-rat measures were put into effect at once, even before the discovery of the first human case of plague. With a few exceptions all the cases may be traced directly or indirectly to the original focus near the Havana water front.

A secondary well-marked focus developed later in the extensive stables of the Department of Public Works in Figuras Street. Two infected rats were found here, the first, April 17, the second, April 24. These are the only infected rats found in Havana. This focus gave rise to six cases.

On account of the character of the stable buildings and grounds, disinfection by the usual methods was futile and the Sanitary Department decided to destroy the infection by fire. The stables and everything within them, except the animals, carts and harness, were converted into ashes, April 25. This radical measure was effective in destroying a very menacing focus of infection. No other case developed from this source, except perhaps Case 25, in which the place of business of the patient, No. 2 Concha Street, was on the route taken by the employees, animals and equipment of the stables destroyed, when they were moving into new quarters.

SANITARY ORGANIZATION

Sanitary measures throughout the Island of Cuba are under the control of the Department of Health and Charities, the head of which is a cabinet officer. The secretary of this department, which is, in truth, a department of public health, is at present Dr. Enrique Nunez, a physician of ability. The actual work of sanitation, however, is in charge of the Director of Health, Dr. Juan Guiteras, and a very capable corps of assistants.

Every municipality throughout the island has a chief sanitary officer reporting to the Director of Health. In Havana the government maintains the well-known "Las Animas Hospital" for the care and treatment of all cases or suspected cases of communicable diseases, which hospital is in charge of the Director of Health, as is also the well-equipped laboratory connected with the department. In normal times a personnel of about 100 men is kept on duty inspecting, fumigating and rat-catching. In times of epidemic outbreaks, as in the present case, this number is very materially increased. An official bulletin is published monthly by the department, containing interesting morbidity and mortality statistics and original articles of value, the more important being published in Spanish, English and French. The general organization of the department makes for quick and efficient work.

The sanitary measures put in force during the present outbreak of plague are directed primarily against the rat and flea and may be considered under the following headings:

INSPECTION

The relation existing between the inhabitants of Havana, the hospitals and the medical profession is such that thorough inspection is facilitated. The Spanish-born population of Havana maintains its original provincial character by becoming affiliated to social and mutual aid societies named after the Spanish provinces from which they come. We thus find the "Gallego" Center, the "Asturian" Center, etc. In addition to these regional centers, or societies, there is a rich and powerful organization known as the "Association de Dependientes" (Association of Employees), to which all Spanish and Cuban employees are eligible to membership, although it is largely made up of the former. The three associations mentioned have a combined membership of about 75,000 men. The importance of these centers from a sanitary point of view is that all these organizations maintain excellent hospitals and dispensaries for the benefit of their members who, when ill, are only too glad to report at once to the medical officers in charge for treatment. These hospitals are known by the euphonious title of "Quintas de Salud," or health villas.

Citizens of Cuba not affiliated with the societies mentioned above, when ill, are entitled to the benefits of the state dispensaries, maintained by the state under the direction of the Department of Health and Charities. The sanitary inspectors of this department respond to the calls made on them by those in need of medical assistance and investigate reports of disease made by the police authorities, taking such action as the case may demand.

The well-to-do are, of course, treated by their own physicians, who in accordance with the sanitary laws and regulations must at once report to the health authorities all cases of communicable diseases. In the present instance strict enforcement of these regulations is made possible by the almost unanimous interest and cooperation of the medical profession of Havana, which is working in entire accord with the Department of Health and which, if anything, is at times too quick in reporting suspicious cases.

From the foregoing it will be seen that inspection is thorough and well under control of the sanitary authorities. All suspicious cases are at once removed to one of the Quintas de Salud or to Las Animas Hospital. Under no circumstances are patients with quarantinable diseases treated at their homes.

DIAGNOSIS

The definite diagnosis of cases of an epidemic disease is secondary only in importance to a well-established inspection service; in fact, it is of equal importance in epidemiologic work. This is well provided for in Havana. All cases of illness of a suspicious nature are reported to the Director of Health, who at once convenes a legally appointed board, known as the "Commission of Infectious Diseases." This commission consists of five members, including the Director of Health. The appointments are non-political and are based solely on high professional standing and recognized diagnostic ability. The findings of the commission are absolute and not subject to review by other authority.

In drawing its conclusions, so far as plague is concerned, the commission depends on four factors, to-wit: (1) clinical symptoms, (2) the microscopic examination of the body liquids, (3) cultures from these, and (4) results of inoculation of susceptible animals.

A diagnosis of plague is never made on the clinical symptoms alone; one or more of the other factors must be positive. With the diagnostic work in the hands of competent men the chances of error are small, but they may occur and in fact have occurred in one or two instances. In each of these cases the commission has demonstrated its sincerity and frankness by revising its diagnosis. For instance, in Case 2, the first three factors were negative of plague and the fourth having also failed to give positive results after the usual time, a negative diagnosis was rendered; yet, when the inoculated animal was killed on the tenth day and the lesions of plague found, the case was at once announced as positive, although the patient was at the time practically well.

DERATIZATION

Since the first outbreak of plague in 1912, deratization has been constantly practiced in Havana. Two weeks prior to the recognition of the first case in the present outbreak it was extensively carried on, owing to the reports of the finding of dead rats by the sanitary inspectors. The work has been actively pushed up to the present time, and all rodents caught or killed are examined for plague in the laboratory of the health department. Over seventy thousand rats have been examined since 1912, and only two found plague-infected, both during the present outbreak, the first, April 17, the last, April 24.

RAT-PROOFING

Havana has the advantage that its buildings are to a great extent rat-proof in structure or can be easily made so. During the outbreak of plague in 1912 almost the entire commercial district was rat-proofed. This work is now being actively pushed whenever it is required, in the infected area or elsewhere.

In accordance with an order recently issued and applicable throughout the Island of Cuba, a fine will be imposed on any person on whose premises rat holes or runs are found. The order goes into effect six months after date of publication.

In connection with deratization and rat-proofing it is interesting to note that the sewerage system of Havana is now practically completed and was put in operation March 1, 1913. It is one of the most complete systems ever devised and the cost of the entire work when finished, including the conduits for surface drainage, will amount to about $23,000,000.

A few of the former sewers in old Havana draining into the harbor are still used in part. They are closely connected with the main infected district and it is quite possible that they harbor rats. They have been thoroughly fumigated, but it is the intention of the sanitary authorities to open them up so as to get an exact idea of conditions.

While the sewerage and drainage systems are excellent in construction and will serve to advance the general sanitary conditions of the city, the best results cannot be expected as yet, for the reason that the house connections are faulty. This is now being attended to. Of the 20,000 houses in Havana, 5,000 have been examined, and when the connections were not properly made the defects have been removed. The work of inspection will continue until all connections are made sanitary.

DISINFECTION

The agents for this purpose are hydrocyanic acid gas, sulphur dioxid, phenoco and a similar phenol disinfecting fluid, steam and fire. In fumigation work hydrocyanic acid has given excellent results and is preferred to sulphur dioxid. The method employed in its use is as follows:

The capacity of the space to be fumigated is first calculated, and the amount of potassium cyanid and sulphuric acid required determined in accordance with the following standard: For every cubic meter, 20 gm. commercial potassium cyanid, 40 gm. crude sulphuric acid, and about 100 c.c. water. The potassium cyanid is divided into convenient parts and each enclosed in three thicknesses of manila paper. A number of earthenware, or better, wooden vessels corresponding to the number of packages of potassium cyanid to be used are then provided and distributed about the building. Into these vessels is poured the aqueous solution of sulphuric acid. All openings having been closed except that of exit for the operators, the packages of potassium cyanid are thrown into the receptacles containing the sulphuric acid, the operators retreating toward the exit, which is sealed when the last receptacle is put in operation. The time of exposure varies from six to twelve hours, usually the latter.

The success of the operation without harmful results to the operators is based on the paper packages of potassium cyanid. As before stated, the chemical is protected by three layers of manila paper bagging, great care being taken that there are *no* holes in the paper, and by actual laboratory experiment it has been determined that from twenty to twenty-five minutes will elapse before the sulphuric acid solution destroys the paper envelope and the chemical action begins setting free hydrocyanic acid gas.

This gives ample time for putting in operation the number of receptacles necessary even in large and irregular buildings. The amount of potassium cyanid in the packages varies, according to the amount and distribution of the space to be fumigated. Packages ordinarily contain 1, 5, 10 or even 20 kg. of potassium cyanid. In actual practice the best and cheapest receptacle has been found to be the wooden barrels used for packing lard.

The effects of hydrocyanic acid fumigation are striking. No living thing seems to escape its lethal action, while inanimate matter is left unscathed. Merchandise, silks and satins, metals, foodstuffs, none are in any way injured by its presence. It is an ideal substance for fumigation, when plague or yellow fever are concerned, but its germicidal power is weak.

For fumigating small spaces such as rat-holes, runs and caves, Dr. Hugo Roberts, Chief Quarantine Officer of Cuba, has devised a simple, cheap and efficient apparatus. It consists of a wooden box 12 by 4 inches with a false bottom with two circular openings into which are inserted two 1,000-c.c. bottles with rubber stoppers, each perforated with two openings to permit the passage of the glass tubing connecting the two bottles and each in turn to the rubber bulb and the outlet tube, to which, for convenience, a glass nozzle may be attached.

The bottle to which the rubber bulb is connected is charged with sulphuric acid diluted with two or three times its volume of water. The bottle to which the rubber tube and glass nozzle is attached is charged with powdered potassium cyanid. By means of pressure on the bulb the acid solution is forced into the bottle containing the cyanid. Chemical action is at once set up and hydrocyanic acid gas rapidly evolved, passing out through the glass nozzle which has been previously inserted into a rat-hole, the open space around the nozzle having been sealed with a dash of cement mortar.

The box is fitted with a movable handle which serves several purposes, to-wit: (1) convenience in carrying about, (2) facilitates the removal of the bottles for recharging, and (3) serves as a rest for the exit tube in order to avoid kinks and the consequent interference with the escape of the gas.

The apparatus may be made of any convenient size. For small rat-holes the size described above is used; for larger holes bottles having a capacity of 5,000 c.c. are employed. In the larger size the air tube is attached to a bicycle pump instead of the rubber bulb.

Larger sizes than this have not been used; but, if necessary, it seems quite possible to greatly enlarge the instrument up to the size, let us say, of the ordinary formaldehyd autoclave, placing it on a truck or carriage so that it can be carried about with ease.

The small apparatus is charged with 150 gm. of powdered commercial potassium cyanid and about 300 gm. of crude sulphuric acid, diluted with three times its weight of water. This is calculated to yield 10 cubic meters of 1.6 per cent. hydrocyanic acid gas. In a confined space the percentage of hydrocyanic acid gas will be materially increased.

The apparatus is now extensively used in the anti-rat campaign in Havana.

Sulphur dioxid is used principally for fumigating sewers and for the purpose of determining their connections with rat-runs and caves. Steam is employed in the disinfection of bedding and clothing, etc., at Las Animas Hospital.

Fire, as previously mentioned, was used to destroy in its incipiency the focus in the stables of the Department of Public Works. Six patients were infected here, and as it was impossible to disinfect these stables by ordinary methods, they were ordered to be burned under the direction of the fire department.

Phenoco and a similar phenol disinfecting fluid are utilized for washing floors, walls, etc. The germicidal power of the former has been standardized according to the methods employed by the U. S. Public Health Service and found to be from fifteen to sixteen times stronger than phenol (carbolic acid).

The modus operandi in the disinfection of a building is as follows:

1. Fumigation with hydrocyanic acid gas.
2. Diligent search for rat-holes, which when found are fumigated with hydrocyanic acid with Dr. Robert's apparatus.
3. Tracing rat-holes, for which purpose, if necessary, floors and walls are removed and opened.
4. Washing floors and walls with phenol disinfecting fluids.
5. Inundation with mild solution of a phenol disinfectant.
6. Rat-proofing.

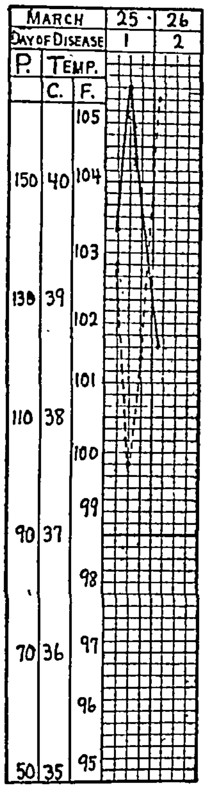
It is interesting to note that no secondary cases have occurred after the disinfection of a locality.

DEPOPULATION AND SANITARY CORDON

One of the most striking features of the anti-plague campaign in Havana has been the depopulation of seventeen blocks, in the center of the commercial district of the city and the throwing of a military cordon about this zone, within which were located the two principal foci of infection. The depopulation was carried out under the authority of a section of the sanitary code which empowers the health authorities to close any house, building or establishment which is considered dangerous to the public health.

The depopulation was practically completed within twenty-four hours. Nothing was removed from the zone. The well-to-do were allowed to go where they pleased after leaving their new address with the sanitary department. Those who were in want, or could not afford to move elsewhere, were sent to the quarantine camp at Trisonia and there maintained at the government's expense.

The entire zone was then disinfected block by block, including the sewers connected therewith, beginning at the point furthest from the harbor and advancing toward the water front. That portion between the lower end of the zone and the wharves was also fumigated. All buildings not rat-proof were made so. Three weeks elapsed before the "zone" was opened up and the inhabitants allowed to return. Taking everything into consideration, the work of depopulation was carried out without undue friction. Of course, there were a number of violent objectors, upheld by a small portion of the press; but on the whole the people affected took the matter sensibly and with good humor.



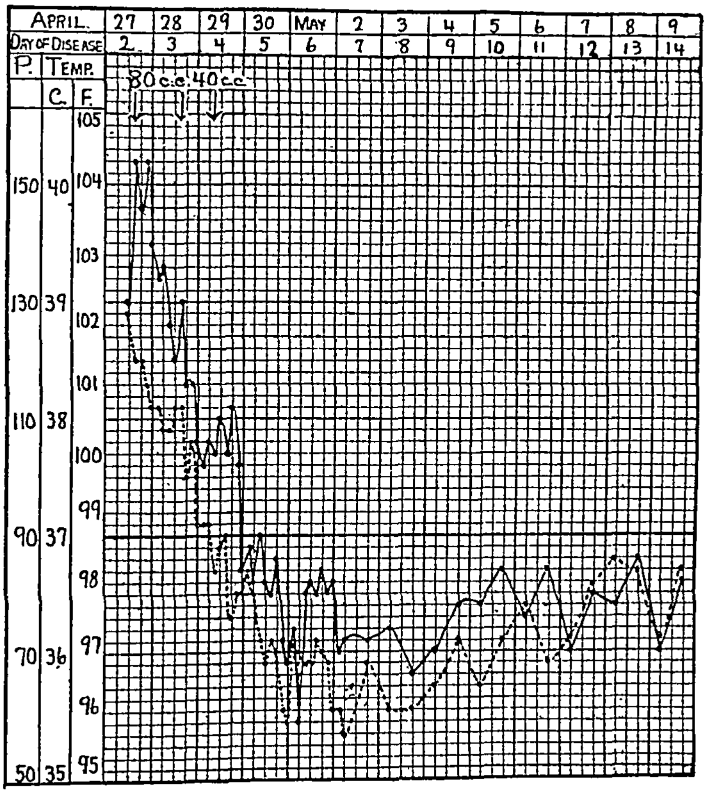


Chart 1.—Clinical chart of Case 5, storehand, aged 12, native of Spain, with septicemic plague. Death in thirty-six hours. In this and the following charts, the temperature is indicated by the solid line and the pulse by the broken line.

Chart 2.—Clinical chart of Case 10, laborer, aged 29, mestizo, Cuban, with bubonic plague. Type of severe case ending in recovery.

INTERNAL QUARANTINE

No restrictions were placed on personal travel. Coastwise vessels are fumigated at Havana and all freight capable of harboring rats fumigated, except such freight as might be certified as coming from interior non-infected points and loaded directly from a rat-proof wharf.

OUTGOING QUARANTINE

Vessels leaving for foreign ports are fumigated for rats by the Cuban authorities on request. The Cuban quarantine regulations require the fumigation of all vessels that have docked at Havana and are bound for Cuban ports. Such vessels are fumigated in the stream immediately before sailing. Hydrocyanic acid gas is used for this purpose with excellent results. Vessels bound for the United States via Cuban or foreign ports are fumigated with sulphur by the Cuban authorities, under the supervision of the U. S. Public Health Service, and a certificate to that effect is issued. A brief summary follows of the outgoing-quarantine measures enforced by the United States Public Health Service against vessels, passengers and cargo bound for United States Ports.

1. Vessels to be fumigated every thirty days. This was continued until about the middle of May. Subsequently the time between fumigations was made fifteen days.

2. All vessels to have approved metallic rat-guards on all lines and to be fended from the wharf at least six feet, gangways to be raised at night unless loading. With the precautions mentioned above, vessels were allowed to dock at rat-proof wharves except during the first few weeks, when they were compelled to anchor in stream. Bills of health were refused to vessels unloading at non-rat-proof wharves unless fumigated in the stream when empty and loading from lighters.

3. Vessels anchored in the bay are required to take the same precautions as above, and all lighters must be removed from the side at night.

4. The fumigation of all parts of the vessel simultaneously without cargo. Amount of sulphur was at first 3 pounds per thousand cubic feet without cargo and 4 pounds with cargo. Time of exposure six to twelve hours, respectively. At the end of April this was changed to 4½ pounds of sulphur and twelve hours' exposure in *all* cases, with the exception that living quarters were given only six hours.

5. Up to April 15, crews were not allowed ashore. Subsequent to this date they were permitted to land between sunrise and sunset. June 26, masters of vessels were given permission to go ashore at all times.

6. Personal health certificates to the effect that the party interested had not been within the infected zone for a period of seven days were issued from March 7 to April 15. After that date only inspection of passengers and the taking of temperature of second-class and steerage passengers was required.

7. First-class passengers in transit were not allowed to go ashore until April 16, when they were permitted to do so between sunrise and sunset. Second- and third-class passengers in transit have not been allowed ashore at any time.

8. No cargo liable to harbor rats has been allowed aboard unless passed by an inspector or fumigated.

9. Fruit coming from non-infected points in crates not rat-proof was allowed to be loaded subject to inspection. The fruit must not be stored in Havana, but must be loaded direct from the cars to the vessels from approved wharves or by means of lighters loading from them.

CLINICAL NOTES ON PLAGUE AS OBSERVED IN HAVANA

With four exceptions all the cases of plague in Havana, including those which developed in Artemisa and San Jose de las Lajas, were observed by me at some time during the illness. There was a total of twenty-seven cases, including the two occurring in the vicinity of Havana. The latter for all practical purposes belong to the Havana series, the infection being clearly traced to that city. Of the total, six cases ended fatally, giving a case mortality of 22.2 per cent., which is very low, lower it is believed than has been registered in other known epidemics of plague.

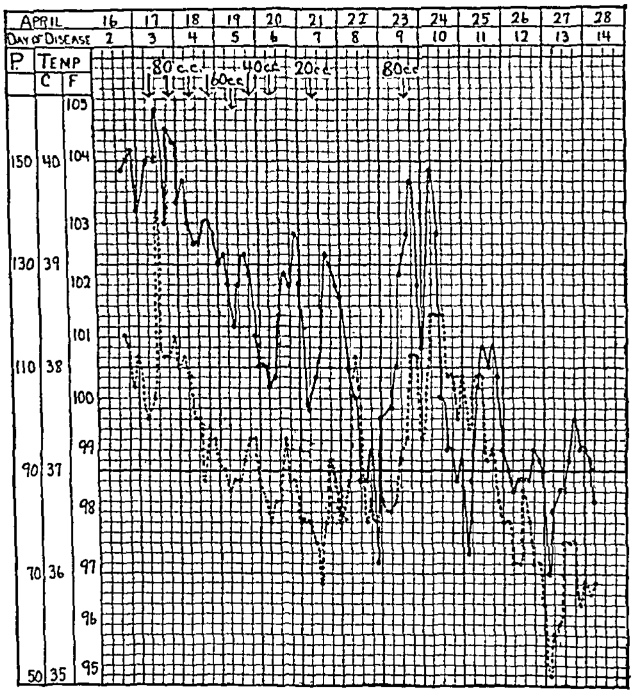

Chart 3.—Clinical chart of Case 13, laborer, aged 20, negro, native of Cuba, with bubonic plague. Type of mild case. Dissociation between pulse and temperature may be noted on the second and fourth days of the disease.

All the cases were of the bubonic type with the exception of Case 5, in which the *Bacillus pestis* was found in the blood, no glandular enlargement being apparent. The case ended fatally within forty-eight hours. Of the bubonic cases all were of the femoral or inguinal variety save two in which the axillary glands were involved. In one of the latter cases the axillary bubo was followed by involvement of the cervical glands near the angle of the jaw, and, strange to say, of the opposite side. This case terminated fatally within seventy-two hours. In one case, No. 11, the initial bubo appeared in the glands above Poupart's ligament.

In the remaining twenty-four cases the bubo first appeared in the femoral region. Later, however, as the disease progressed, the inguinal glands above Poupart's ligament became involved, and in the majority of the cases the surrounding cellular tissues showed distinct signs of infiltration. As a rule the buboes were very painful and tender to the touch. With two exceptions the buboes suppurated and were opened, the healing process thereafter being long and tedious. There have been no cases of pneumonic plague.

Clinical charts of Cases 5, 10 and 13 are herewith appended. They are interesting as showing three different types of plague. Chart 1 represents a septicemic case ending in death in thirty-six hours. Chart 2 records a typically severe case ending in recovery. Chart 3 shows a mild case. In some of the first cases, a dissociation between the pulse and temperature, such as occurs in yellow fever, was observed. A study of the entire series of cases shows, however, that this symptom is not at all constant. Albuminuria was present in all the cases. The amount of albumin was greater than that found in the hyperpyrexia of typhoid and malarial fevers, and the presence of epithelial casts shows that the kidney is seriously involved. The amount of albumin, however, never even approaches that found in yellow fever, with the same febrile movement, that is from 39.5 to 40.5 C. (103.1 to 104.9 F.).

As in other acute infectious diseases, plague may manifest itself in a very mild form, and may be entirely overlooked unless all means at command are exhausted before determining the diagnosis. Cases 2 and 26 of the Havana series are excellent examples of this. In both it was only by painstaking inoculation and cultural tests that the true nature of the disease was finally established.

TREATMENT

The treatment has consisted of intravenous administration of massive doses of Yersin serum, 80 c.c. being administered twice daily during the first three or four days of the disease, or in fact so long as the temperature remains above 39 C. (102.2 F.), the doses diminishing gradually as the temperature falls. Over 500 c.c. of Yersin serum have been administered to one patient in divided doses. The height of the temperature is the guide for the quantity and frequency of serum administration. After suppuration has occurred, and the temperature is wholly or in part due to this process, the fever no longer serves as a guide, and in fact it is found better then to stop the serum altogether. The ill effects of these large doses of serum are counteracted by the administration of calcium chlorid, 1 or 2 gm. daily.

This treatment has given excellent results, as may be seen from the case mortality, which is, as before stated, but 22.2 per cent.

Other general symptoms are treated as they arise, depression by stimulants, principally strychnin; irritability and other cerebral symptoms, by anodynes, particularly drop doses of tincture of opium, diminished renal activity, by hexamethylenamin. Warm wet applications are applied to the bubo, which is opened so soon as suppuration is apparent.

CONCLUSIONS

The following conclusions, I think, are warranted from the above résumé of the history of the late outbreak of plague in Havana:

1. That plague, like other epidemic diseases, may be controlled and eradicated with comparative ease if the health authorities are given the necessary legal and financial power to carry out sanitary measures.

2. That in antiplague work passenger traffic need not be interfered with. In other words, the human plague case is a negligible factor in a well-organized antiplague campaign.
3. That the measures adopted by the U. S. Public Health Service to prevent the introduction of plague from Havana into the United States were effective.
4. That the intravenous administration of large doses of Yersin serum during the active infective period of the disease seems to be the best mode of treatment known to us at present.

CYSTIC ODONTOMAS *

G. B. NEW, M.B., (Tor.),
ROCHESTER, MINN.

The subject of cystic odontomas has not received in this country the same study that it has in England, Germany and France. The importance of the subject is readily appreciated when one considers the marked deformities of the face and jaws that accompany these growths, which early diagnosis and thorough operation might have eliminated in many cases.

Cystic odontomas will be considered under two classes—the simple cysts and the adamantinomas. The simple cysts are again divided into two types: Type A, including the cysts commonly called dental or root cysts, and Type B, those usually called follicular cysts and containing a partially formed tooth. The term "follicular" cyst used for the second type is misleading in that one takes for granted, without knowing definitely, that this type is developed from the follicle of a tooth. The term "dentigerous" cysts is used quite loosely and may refer to either of the foregoing types of simple cysts. For this reason, it has not been used in my classification.

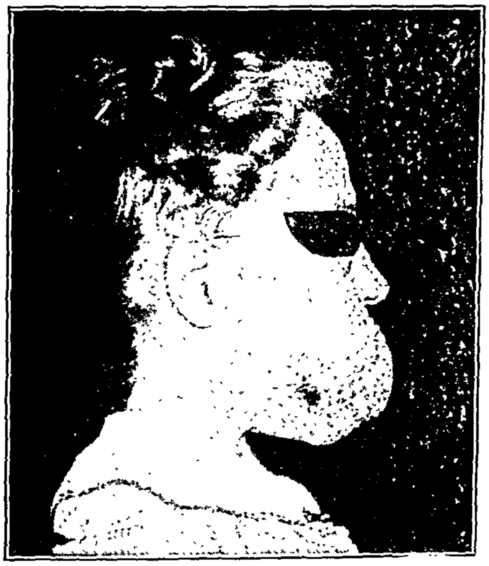

Fig. 1 (A 89376).—Adamantinoma. Woman, aged 50. Duration of tumor, twenty-one years.

Twenty-six cystic odontomas are herein reported from the Mayo Clinic. Twelve of these are simple cysts of Type A; six are of Type B, and eight are adamantinomas.

SIMPLE CYSTS OF TYPE A

The simple cysts (Type A) are the most common cysts of the jaws. Because of their little surgical importance, they have not received the attention which has been given to other cystic odontomas. Magitot[1] in 1872 published the first important work on the subject of cystic odontomas, and attributed their origin to the development of the embryonic dental tissue. Malassez[2] in 1885 found masses of cells about the roots of teeth in the jaws of adults and concluded that these were the remains of the dental ridge, the epithelial cord and the outer layer of the enamel-organ. These cells may be found near the teeth and are sometimes found deep in the jaws. Malessez called these masses of cells *débris épithéliaux dentaires,* and proposed the theory that all cystic odontomas were derived from this group of cells. This theory is the one most commonly accepted.

According to Scudder,[3] this type of cyst is found more commonly in the upper jaw in the incisor and bicuspid regions. Of the twelve cysts of this series, six occurred in the upper jaw and six in the lower. Of those in the upper jaw, four occurred in the incisor region, one in the bicuspid region, and in one case the location was not noted. In the lower jaw, three occurred in the incisor region, two in the bicuspid region, and one in the molar region.

The typical mammalian dentition consists of forty-four teeth, and man has but thirty-two, a third incisor, a third bicuspid and a fourth molar being missing. The most frequent location for the appearance of supernumerary teeth is in the upper jaw in the incisor and bicuspid regions. Whether these teeth are a reversion to the earlier types in the mammalian dentition or simply mishappenings is a questionable point among those who have made a thorough study of the subject. It is interesting to note that this type of cyst and the supernumerary teeth most frequently occur in the same location, which might suggest that these cysts are derived from supernumerary anlagen.

The theory has been held for some time that these cysts develop from irritation or stimulation. The irritating factor may be the eruption of a tooth or some form of peridental inflammation. These cysts are frequently found in connection with the dead roots of teeth and thus the irritative factor, necessary to stimulate their growth, is accounted for.

Simple cysts of Type A occur at almost any age. Of the twelve cases reported in this paper, the youngest patient was 12 years of age and the oldest 70. The cyst is usually about the size of an English walnut, but may attain great dimensions, and in the upper jaw, simulate an empyema of the antrum. In the lower jaw it may become as large as an orange. The cysts from our series varied in size from that of a cherry to that of a small lemon. Witzel[4] found tumors the size of a pea and smaller about extracted teeth. They were placed sometimes near to and sometimes distant from the root of the tooth. They contained fluid and had an epithelial lining indistinguishable from a larger cyst. The cysts have a smooth mucous membrane covering in the mouth; the wall varies in thickness and consists of a thin shell of bone (Fig. 5).

SIMPLE CYSTS OF TYPE B

Malassez[2] believes that this type of cysts also originates from cells that he describes in the jaws. Bland-Sutton,[5] however, believes that this type simply represents an expanded tooth-follicle.

[5] Bland-Sutton: Tumors Innocent and Malignant, New York, Cassell & Co., 1901.

These cysts occur in either jaw with about equal frequency and usually in the bicuspid and molar regions.

Of the six cases in our clinic, three were found in the upper and three in the lower jaw. Of the three in the upper jaw, one occurred in the bicuspid region, one in the molar region, and in one case the location was not noted in the history. Of the three in the lower jaw, one occurred in the bicuspid region, one in the anterior part of the jaw, and one in the molar region.

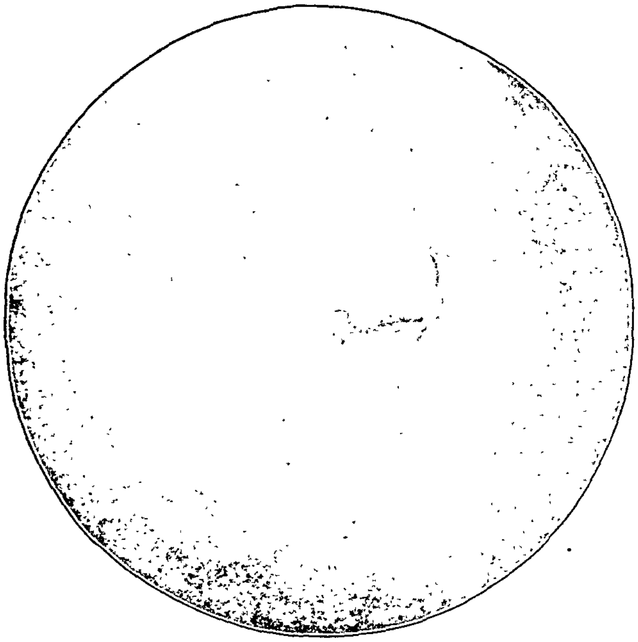

Fig. 2 (23705).—Roentgenogram of case in Figure 1, showing entire absence of ramus of jaw on right side and the tumor extending across midline to bicuspid region on left side.

This type of cysts occurs during or shortly after the second dentition, except those in connection with the third molar, which develop later in life. Although this fact is commonly known, this type of cyst may not cause symptoms or be noticed until later in adult life.

Of our cases, other than those in which the cyst occurred in the third molar region, the ages of the patients were 3, 14 and 28 years; of those in the third molar region, the ages were 27, 34 and 37 years.

It is noted that a tooth is missing from the set and a partially developed one found in the cavity of the cyst. The crown of the tooth is usually complete and the root partially formed. These cysts occur about a partially developed permanent tooth and are rarely seen about a supernumerary tooth.

In one of our cases the cyst occurred in a man 69 years of age. He had had a tumor of the lower jaw near the angle for forty-two years, and during the last six months it had increased in size and the surface had become ulcerated in the mouth. The roentgenogram showed a cyst with a partially developed molar tooth. A specimen from the growth, on microscopic examination, proved to be epithelioma. The extensiveness of the growth and the glandular involvement made the condition inoperable.

This type of cyst has similar characteristics as to size as the cysts of Type A. The wall consists of thin bone and the mucous membrane covering in the mouth is quite smooth.

ADAMANTINOMAS

The adamantinomas, on account of their greater surgical importance and their interesting features pathologically, have given rise to more study than the other types of cysts. Falkson[6] in 1879 held that, in the formation of enamel-organs for the several teeth, there was a surplus of those formed and that these additional dental germs were the origin of the adamantinomas. Malassez' theory as to their development from the epithelial masses found in the jaws is accepted by most observers. Kruse[7] agrees with Malassez as to the origin of the cysts and reports three cases, each one typifying different stages in the development of the cells of the enamel-organs. Büchtemann[8] and Kolaczek[9] believe that these tumors originate from the mucous membrane or from the mucous glands of the mouth. Bland-Sutton[5] and others hold that they are formed from the oral mucous membrane. Bland-Sutton's argument against Malassez' theory is that they occur in middle life and that if they were derived from the embryonic enamel-organ, they should occur at an earlier period in life. Hesse[10] agrees with Falkson[6] as to the origin of these tumors from a surplus of enamel-organs.

The adamantinomas are most frequently seen in the lower jaw. Lewis[11] states that they are seen eleven times more frequently in the lower than in the upper jaw. The bulk of the tumor-mass is usually at the angle of the jaw, extending upward to the ramus and forward into the body of the jaw. Sometimes the entire ramus is cystic with the tumor extending across the midline to the other side of the jaw. These tumors may originate in the molar or bicuspid regions, but are rarely seen originating from about the anterior teeth (Fig. 2).

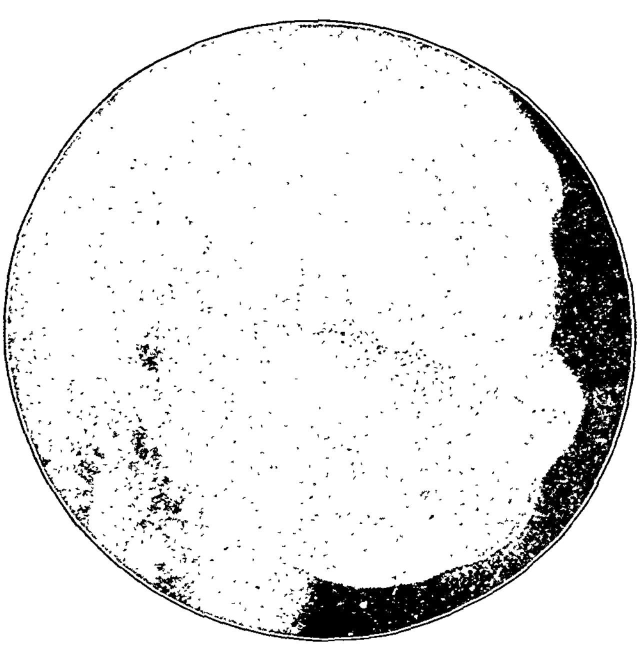

Fig. 3 (13523).—Adamantinoma in woman, aged 22. Duration of tumor, eight years. Tumor involving left half of lower jaw.

[11] Lewis: Surg., Gynec. and Obst., January, 1910, p. 28.

I have been able to collect nine cases in which the tumor occurred in the upper jaw, two from the Mayo Clinic. In only four of the cases reviewed in the literature were there definite data as to the location in the jaw. Four of the nine occurred in the posterior part of the jaw and two in the cuspid region. These cysts may originate close to the alveolar border or may start from deep within the jaw. Of the eight cases of adamantinomas from our clinic, six occurred in the lower jaw and two in the upper. Of the tumors in the lower jaw, in four the main mass was located in the angle of the jaw, in one in the molar region, and in one in the bicuspid region. Of those in the upper jaw, one occurred well back in the molar region and one in the cuspid region (Fig. 1).

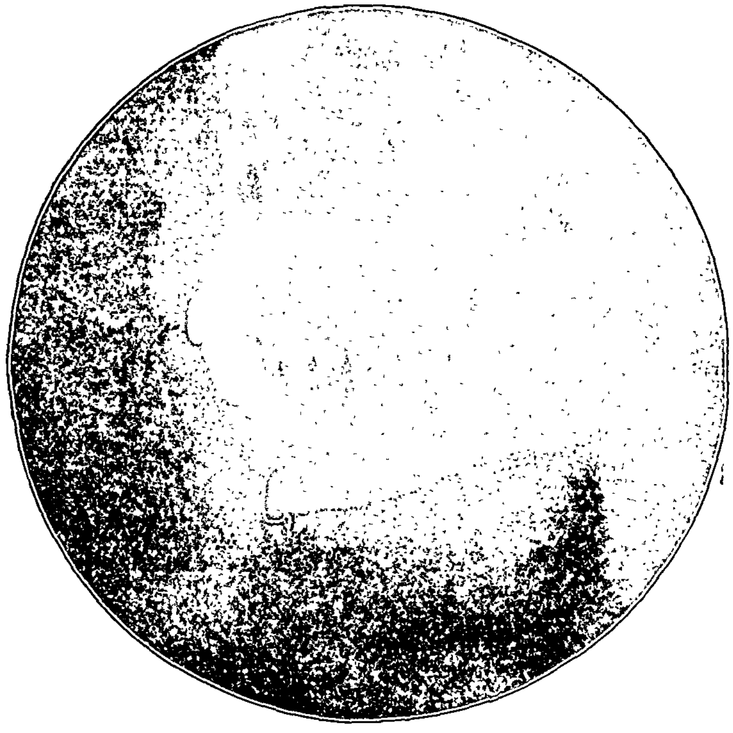

Fig. 4 (13523).—Same case as Figure 3, showing transplanted rib in place after resection of tumor by Dr. Judd. Transplant healed nicely.

These cysts may develop at any age. Massin[12] reports a case in a new-born infant and cases have been reported late in adult life. Lewis[11] states that the average age of the patients in the seventy cases which he collected in the literature was 33. The average age of the patients in our group of cases is 27¼ years. Of the six cases from the literature in which the tumor occurred in the upper jaw, the average age of the patients with occurrence in the molar region was 33½ years, and of those with occurrence in the cuspid region, 16½ years.

Stumpf[13] says that if either of the theories which have been advanced for the etiology of the formation of these cysts is accepted, one must assume some additional irritant factor as necessary in their production. The lower molar region receives more irritation than any other locality in the mouth. It is an accepted fact that the lower third molar is more difficult to erupt and more frequently impacted than any other tooth in the mouth. It is interesting to note that it is in this region and at the average age of 33 years during or just at the time of the eruption of the lower third molar that these cysts occur; and, also, that of the cases in the literature in which the upper jaw was affected, the average age of the patients having adamantinomas in the molar region was 33½ years, while that of patients with involvement of the cuspid region was 16½ years. This suggests that the eruption of the teeth may play an important part in the chronic irritation which is probably necessary to stimulate the growth of these tumors. If these conditions develop from supernumerary anlagen, the different locations in the molar region may be explained by the fact that, according to Black,[14] the supernumerary molar tooth may occur in any location posterior to the first molar. The adamantinomas are sometimes associated with cysts containing partially formed teeth, but not frequently enough to make this a factor in the etiology.

It is difficult to obtain conclusive evidence of the association of the eruption and impaction of teeth to adamantinomas, as most histories are not of sufficient detail on this point. Hesse[10] in 1912 reported a case in which a lower third molar was found in connection with an adamantinoma, and believes that from a study of this case he will be able to find out more about these tumors. Two of the adamantinomas in our clinic were associated with unerupted third molars, one in the upper and one in the lower jaw.

Of the seventy cases that Lewis collected from the literature, the average duration of symptoms was eight and one-half years. The duration of the symptoms in our cases was from ten months to twenty-one years. Most of the cases were of more than ten years' duration; but the exact duration of these tumors is difficult to determine on account of the long standing of the condition.

None of the cases reported in this paper had any glandular enlargement.

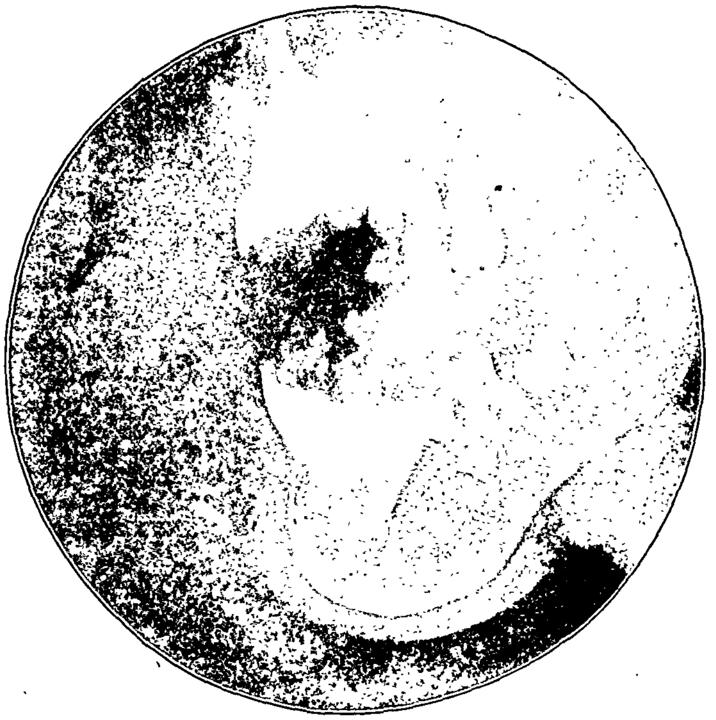

Fig. 5 (12017).—Girl, aged 10. Duration, four months. Simple cyst, Type A, involving anterior of lower jaw.

These tumors present a smooth mucous membrane in the mouth unless they are infected. The wall of the cyst consists of a thin layer of bone. Crackling may be elicited in some areas, on pressure, where the bone is thin, and fluctuation may be found in others. These tumors may give rise to great pain when they are of large size, because of pressure of enclosed fluid. One of our patients, who had had a tumor for twenty-one years, for some years, in order to relieve the pain, tapped the cyst herself, as the fluid accumulated, by means of a sterilized hat-pin.

PATHOLOGY

The lining of the simple cyst, Type A, consists of a layer of fibrous tissue and a thin layer of flattened epithelial cells. In the older cysts the latter layer may not be present, owing probably to the pressure of the enclosed fluid. Barrie[15] in 1905 reported a case of dentigerous cyst which was probably a simple cyst, Type A, with typical adamantine epithelium, with no down-growth, lining the cyst. This was the first case reported with this type of epithelium forming the wall of the cyst.

The lining of the simple cyst, Type B, consists of a fibrous tissue layer. Some observers have reported an epithelial lining for this type of cyst also.

The adamantinomas on section present solid and cystic areas. The cystic areas vary in size from that of the head of a pin to that of an English walnut. They appear to have a smooth lining, and fibrous or bony septa are seen separating the various cysts. The cysts contain a thin yellowish fluid. The solid areas have a red tint and present a granular appearance, owing to the many minute cysts.

Microscopically, the solid areas consist of a fibrous tissue stroma and columns of epithelial cells. These columns may be elongated, rounded or arranged in the form of acini, and may present many irregular forms. Two types of epithelial cells are found in these cell columns: the typical columnar cell with the nucleus placed near the pole away from the stroma, and the differentiated cells from this type—the polygonal cell and a stellate cell which form the main mass of the epithelial columns. These cells are analogous to the cells that form the enamel-organ. Areas of transitional forms from the solid cords to the small cysts are seen. The stellate cells are seen undergoing disintegration and their place being taken by cyst-cavities, at first quite small and then becoming larger. Stellate cells gradually disappear and are replaced by the fluid of the cyst. As the cyst increases in size, the columnar cells are alone left to line the cyst, while in the yet larger cysts these have disappeared and the wall consists of fibrous tissue only (Figs. 6, 7, 8, 9, 10 and 11).

DIAGNOSIS AND TREATMENT

The diagnosis of the cystic odontomas, when the facts already noted are considered and with the aid of the roentgenogram, is usually not difficult. The roentgenogram will show a partially developed tooth, a unilocular cyst or the septa in the multilocular variety. The differential diagnosis from a giant-cell sarcoma is usually the most difficult, and this has frequently to be made at the time of operation or by microscopic examination.

The treatment of the cysts of the first group requires only a thorough curetting of the wall and packing the cavity with gauze. In the larger type, resection may be required to extirpate the tumor. The adamantinomas, however, require more radical treatment since the simple curetting of the cyst does not permanently cure the condition if a small area of the tumor is left. In time the condition recurs. A resection of the jaw should be made, if possible; in this way all the tissue of the tumor may be removed. Different appliances have been used, including metal splints to hold the fragments of the jaw in position after resec-

tion, but the transplantation of a portion of rib seems to be the most satisfactory (Figs. 3 and 4.)

Recurrences are frequently noted in these tumors, especially when the treatment has been conservative. Bloodgood[16] reports twelve cases of adamantinomas. One case was inoperable, and in eleven cases resection of the jaw was done. Nine of these patients were well from one to twelve years. There was one recurrence after the patient had been well for eight years. One died following excision of a huge tumor involving both sides of the upper jaw.

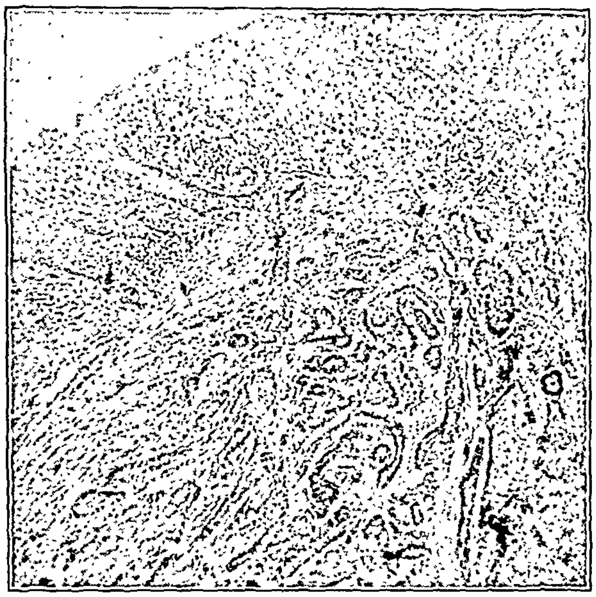

Fig. 8 (A 68435).—Adamantinoma. Down-growth of the columns of epithelial cells and the various forms these take, surrounded by connective-tissue stroma.

Of the eight cases reported from our clinic, all of the patients have been operated on within the last two and one-half years, so that the final results cannot be given. One patient died of heart-trouble eight months after the operation, and two have been operated on within the last six months. In one case the tumor recurred, but the patient has now been well more than two years; one recurred after two years and the patient has been reoperated on for the recurrence within the last six months. In one case, on account of the extensiveness of the tumor and the fact that the cyst had fibrous walls which involved the entire half of the jaw and the ramus and extended across the midline, resection was impossible. The tumor was opened and the cysts curetted. Several small cysts have appeared since the operation. Two patients have had no recurrence; one case is of eighteen months' standing and one of two years'.

ABSTRACT OF DISCUSSION

Dr. F. B. Moorehead, Chicago: The classification Dr. New suggests is not entirely satisfactory. Until we know more about their pathology, we are not likely to have a scientific classification of these jaw cysts. In the types which Dr. New classifies as Class A and Class B, the questions are whether one originates from embryonic remains and whether the other is due to irritants, as infection through tooth roots, etc. There is also a question of the histology of these two types of cysts, whether one contains an epithelial lining and the other does not. Some men believe that the cyst due to infection does not contain any epithelial cells, while the other type of cysts does. It is difficult to get a good specimen for examination from the infection type of cyst for two reasons: first, these cysts are usually the seat of a secondary infection, and the epithelial lining is frequently destroyed; secondly, the cyst-wall may be very thin and may be badly torn when removed, so that a good specimen is difficult to obtain. In an uncomplicated infection cyst we find a characteristic straw-colored stringy fluid, which contains cholesterin, showing that there has been cell degeneration. I am certain that these cysts, which are infective in origin, do contain epithelial cells, and that when one is fortunate enough to get a good section he will find a definite epithelial lining. From the clinical side, there are two things to be borne in mind in dealing with these cysts: first, they may encroach on the inferior dental nerve in the lower jaw, in the upper jaw on the maxillary sinus. The bone is destroyed in all these cases by pressure apathy. One, therefore, must bear in mind the fact that in operating on these cysts in the upper jaw, he is quite likely to get into the maxillary sinus, or even the nasal sinus, and also into the inferior dental canal in the lower jaw. In many cases the inferior dental nerve is entirely destroyed and analgesia of the tooth-supply of this branch may persist for a long period of time. In removing these cysts one should remove a sufficient amount of the external wall to restore the normal contour to the parts and no more. Whether there has been a bulging of the walls on either the upper or lower jaw, the wall should be removed down to a point where the normal contour is restored.

Dr. T. L. Gilmer, Chicago: A better classification of cysts of the jaw is desirable; still we should be a little slow in making radical changes until we know more of their pathology and also the histology of the elements which make up such cysts. The origin of dentigerous cysts is certainly quite different from that of the other class of cysts designated as infection cysts. Eve expressed the opinion that multilocular cysts were due to inclusion of the epiblast by the mesoblast. It seems reasonable to suppose that persistent embryonic epithelial remains of the enamel-organ cord may be stimulated by infection and cause it to proliferate, resulting in the so-called infection cysts which undoubtedly are associated with infected teeth. I am not sure that such cysts should be designated as infection cysts; they are caused by infection in the jaws about the roots of teeth, but are not necessarily infected at first, but may become so afterward. I have made microscopic examination of the lining of the walls of these cysts and found in some of them epithelial cells. In others, in which there has been much thinning of the walls of the

cyst from long standing, the epithelium is seemingly lost. Concerning the surgical treatment for cure in the cases spoken of by Dr. New, in which he recommended resection of the jaw, I believe that I can judge very certainly by a good view of the bone, whether I have gotten beyond the area involved. I doubt if we should ever make exsection of the mandible except in positively malignant growths involving the whole thickness of the mandible. If even a little bone can be left to support the jaw it will prevent the terrible disfigurement of the patient which results from complete separation of the jaw. If the case is carefully watched the more radical operation may be done if there is indication of recurrence. I feel that we are justified in this method except in the most malignant cases.

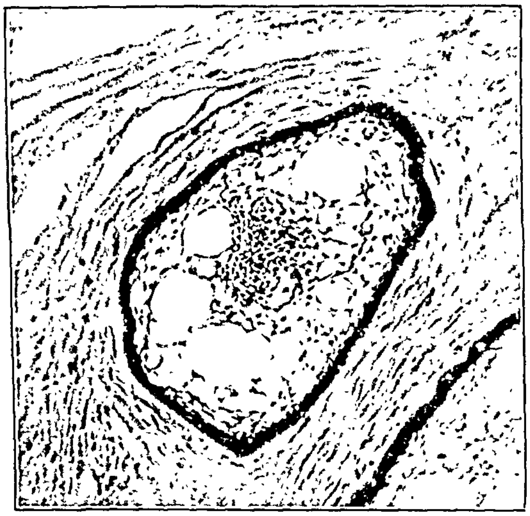

Fig. 10 (A 59772).—Adamantinoma. Early cyst formation by the disintegration of the differentiated cells.

Dr. M. I. Schamberg, New York: I have two pictures, one showing enlargement of the mandible from the cuspid region back toward the ramus; the second showing a tremendous destruction of the jaw similar to that described by Dr. Moorehead. In this case we operated after the method condemned by Dr. Moorehead and the result can best be determined by the roentgenogram, which was made a year and a half after the operation and shows complete regeneration of the bone throughout its entire extent. These cases I have endeavored to follow up in every instance so as to know definitely the results obtained. The method of procedure was to make an incision along the upper border of the alveolar plate, after taking out the involved teeth. We allowed the third molar to remain as a possible abutment for bridgework later. After dissecting the mucous membrane away along the buccal side and cutting away a thin layer of the bone about the lower border so as to get access to the entire cystic cavity, the whole was removed *en masse* and by microscopic examination we found it contained epithelial cells. The cavity was then packed with iodoform gauze until the cavity filled with granulation tissue which has since been replaced by bone structure. That is the method that I employ in almost all of these cases.

In a case of multilocular cyst Dr. Jerrigan, the surgeon, contemplated exsection of the jaw. When I saw the patient I advocated the operation which I performed of making an incision along the lower border of the jaw, starting at the lobe of the ear and carrying it along the lower border to a certain point. This patient was a prominent man in his town, and felt that the loss of his jaw would prove a serious handicap, and I am sure that the recovery in this case will be as permanent and as satisfactory as in the other case. The roentgenograms are a most important step in the diagnosis and prognosis of the cases and as an aid in outlining the operation necessary.

Dr. Theodore Blum, New York: With regard to operations for cysts, Dr. Schamberg did not mention that he is performing a special operation in the upper jaw. This operation is what is known as Jones' operation. In contrast to the other operations mentioned this does not involve the removal of the entire cyst wall but only its outer portion. Instead of opening and removing the cyst wall entirely and then allowing the wound to heal by granulation, only the major part of the outer wall of the cyst is removed. First, an incision is made, low instead of high, because it gives better access to the cavity. A good portion of the outer wall should be taken away so as to flatten out the cavity as much as possible. The teeth have been taken care of, the flap above and the one below are turned in and either retained by gauze packing or sutured at both points. It only takes three or four days for the mucous membrane of the mouth to unite, and we can discharge the patient with instructions as to cleaning the mouth with a syringe. This is a valuable operation in hospital work because the patient can be dismissed for weeks. This operation is frequently performed by Dr. Partsch of Germany, who is an authority on this subject. In the case of large cysts when there is danger of fracture, Dr. Partsch advises that, before operating, an appliance be put in the mouth consisting of a sliding joint, and in case of a subsequent fracture the fractured parts are held in place on each side of the jaw.

Dr. C. K. Teter, Cleveland: In following up cases and operations, this is one of the most satisfactory operations we can accomplish because of the unlikelihood of recurrence. A few cases will bear out Dr. Schamberg's idea that the bone will regenerate on the lower jaw. In one case, in a young man 18 years of age with an enormous cyst on the right side of the maxilla which extended from the angle of the jaw to the lower border of the first bicuspid tooth, the cyst involved not only the third but also the second molar. An incision was made near the ridge of the jaw and it was comparatively easy to remove the outer wall of the cyst together with the fibrous socket which came out practically *en masse*. Eight months afterward a roentgenogram was taken and showed a practically reformed mandible, which was very gratifying to the patient as well as to me.

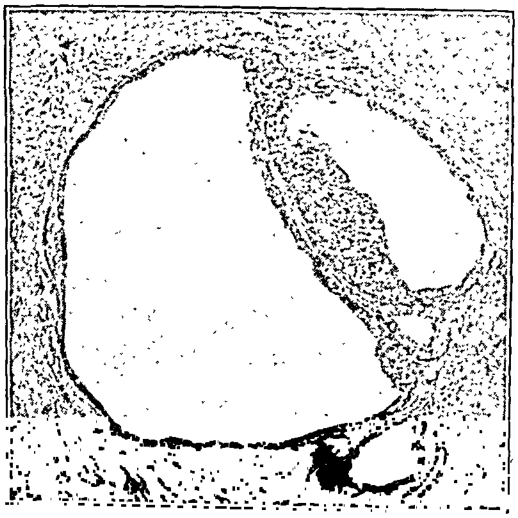

Fig. 11 (A 68435).—More advanced stage in formation of a cyst. Very few differentiated cells are left. The cyst is lined by a layer of columnar cells.

In another case a multilocular cyst in the region of the upper first and second bicuspid about the size of an English walnut, contained, besides fluid, twenty-four small pieces of illy formed cementum and enamel about the size of grains of rice.

MESOTHELIAL TUMORS OF THE JAWS *

ROBERT H. IVY, M.D., D.D.S
Assistant Instructor in Surgery, University of Pennsylvania
PHILADELPHIA

Within the past year it has been my privilege to study, clinically and histologically, a considerable variety of mesoblastic neoplasms of the oral cavity. Most of these cases occurred in the oral surgical service of Dr. M. H. Cryer, to whom I am indebted for the opportunity of reporting them.

Most of the growths under consideration fall into that group known under the common term "epulis," a name meaning from its derivation anything on the gum. An epulis may be described as a circumscribed connective-tissue growth from the alveolar ridge, which is covered over by the normal mucous membrane, except as the latter may undergo secondary ulceration due to pressure necrosis, infection, etc. (Occasionally, growths clinically classified as epulis may be found to be epithelial in nature, for example, papilloma, epithelioma, etc., but these will not be considered here.) Under this broad heading, therefore, many clinical and pathologic varieties of mesoblastic tumor may be included.

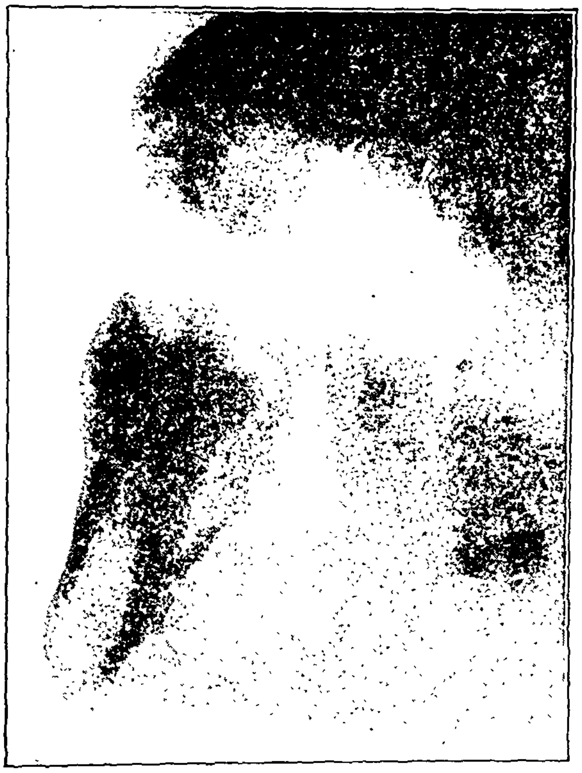

Fig. 1.—Roentgenogram showing giant-cell myeloma. (Cryer.)

The most obvious clinical characteristics of an epulis and those which give the most reliable information as to its pathologic nature are (a) consistency, and (b) rate of growth. Thus we have the hard epulis and the soft epulis. The hardness is in the new tissue itself. In the soft variety there may be a hard shell of bone covering a portion of the tumor, but the tumor tissue itself is soft. The hard variety of epulis is nearly always very slow in growth, and alters in size but little in months or even years. There is usually quite a sudden line of demarcation where the bulging of the new growth extends beyond the normal contour of the gum. It gives the impression of arising from the surface of the underlying alveolar process. In color, the gum tissue covering the tumor may be slightly reddened, though it generally differs but little from that of the normal gum.

The soft form of epulis on the other hand, is usually rapid in growth, often increasing greatly in size in a few weeks. The bulging beyond the normal gum-contour, in the deeper parts of the swelling at least, generally occurs gradually while one may distinctly recognize the origin of the growth as being from the interior of the bone. A portion of the tumor may be covered by a bulging shell of bone. In color, these tumors are generally a dusky red. In this variety of neoplasm, the Roentgen ray frequently shows a space in the bone as clean-cut as though it had been drilled through with a large caliber bullet (Fig. 1). Epulic growths may be sessile or slightly pedunculated, and vary in size, occupying the space of one, two, or several teeth, which are often considerably displaced or loosened.

The two clinical types of epulic tumor present marked differences in histologic appearance.

The hard variety of epulis is fibroma pure and simple. Microscopically, we see an outer layer of normal stratified squamous epithelium and submucosa, while the deeper portion of the growth consists of an interlacing network of fibrous tissue (Fig. 2). Occasionally there is evidence of myxomatous degeneration, and sometimes of bone formation. These growths spring from the periosteum lining the alveoli.

The soft epulic tumors are generally grouped pathologically under the giant-cell sarcomas or myelomas. Histologically, beneath the covering mucous membrane there is a stroma of fibrocellular tissue resembling fibrosarcoma. Scattered throughout are the giant-cells, which vary in size and have numerous nuclei grouped toward the center of the cell. Small masses of bone and cartilage may be found (Fig. 2).

There is considerable confusion as to the proper classification of these growths, the literature both surgical and pathologic presenting many divergent views. Thus Bland-Sutton[1] terms the growth a "myeloma or red-marrow tumor." Nichols[2] regards it as a "bone-marrow or medullary sarcoma." Owen[3] describes the same thing as "myeloid sarcoma." Other writers prefer to use the term "myeloma" rather than giant-cell sarcoma. The confusion is further increased by finding in works on pathology an entirely different growth described as myeloma, which contains no giant-cells whatever. Thus Mallory[4] describes the myeloma as a "tumor which arises within the bone-marrow and which is peculiarly characterized by causing the presence of albumose in the urine. . . . The cells are of medium size and irregularly spherical." Nowhere does he mention the presence of giant-cells in this growth. Mallory[5] further says that the term "giant-cell sarcoma" should be abolished. He states that at least two types of giant-cells are found in tumors, one resulting from multiple mitosis and signifying rapid growth, and the second, which is found most commonly in new growth involving bone. It is the latter type that is most frequently met in these giant-cell tumors of the jaws. Mallory looks on them as "foreign-body giant-cells, similar to the osteoclasts of normal bone, and are due to the fusion of endothelial leukocytes attracted into the tumor by the

presence chiefly of lime salts which they dissolve and remove. They signify usually disintegration of bone. . . . The tumor containing foreign-body giant-cells should be classified according to the nature of the other cells present in the tumor; the foreign-body giant-cells should be disregarded. They do not signify either rapid growth or malignancy." From clinical observation of cases showing these giant-cells, we agree with Mallory that they signify neither rapid growth nor malignancy, but would go still further and say that their presence rather tends to show that the tumor is non-malignant in most cases. For we have seen several cases, which, if the giant-cells were excluded, from the histologic appearance of the remaining tissue would have to be classified as malignant sarcomas, and yet in which simple removal of the growth itself has resulted in perfect cure. The presence of giant-cells would therefore seem to be an indication that the malignancy of the tissue has been modified in some manner, and that they thus have considerable significance from the point of view of prognosis. It is unfortunate that there is no suitable name, agreed on by all, for this frequently occurring growth.

There is, however, a tumor of the jaw rich in foreign-body giant-cells, which cannot be regarded as clinically benign. This type has recently been described for the first time by Whitman.[6] In the new type there is a proliferation of the vascular endothelial cells which extend to form the main elements of the tumor. Scattered throughout are numerous foreign-body giant-cells, a great many of which lie within the lumina of blood-vessels. Whitman concludes that myeloid or giant-cell sarcomas can be divided into two groups, the new group consisting of tumors very closely resembling the true myeloid sarcoma (that is, the form first described), but which are clearly of endothelial origin and the giant-cells of which are usually intravascular.

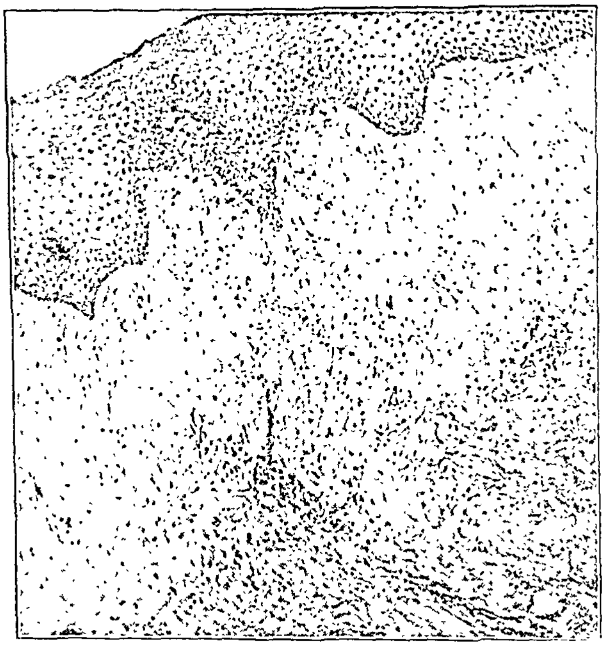

Fig. 2.—Histologic appearance of section from fibrous epulis. Note interlacing network of fibrous tissue.

We believe that the recognition of two distinct types of giant-cell myeloma is not only of pathologic interest, but is also of considerable clinical importance. I think we have all had the experience of cases in which a pathologic report of giant-cell sarcoma was rendered, and yet which pursued quite divergent clinical courses subsequently, in one case simple removal resulting in cure, in another followed by recurrence of the growth. From a study of our cases and comparison with that reported by Whitman, I believe that this clinical difference is due to difference in structure. Ordinarily, giant-cell tumors of the jaws are not to be regarded as clinically malignant, that is, they are sharply defined from the surrounding healthy tissue and shell out easily from the cavity in the bone. They produce no metastases, and do not recur after simple enucleation. Histologically and clinically, four of the cases of giant-cell tumor to be reported were of the usual type (Cases 2, 3, 4 and 5). The other case (Case 6) corresponds closely to the new type described by Whitman, and in its clinical manifestations differed markedly from those belonging to the usual form. There was an extensive growth of the upper jaw, involving the maxillary sinus, not sharply circumscribed, and which recurred several times after apparently complete excision. Microscopically (Figs. 4 and 5), the growth consisted of a proliferation of the capillary endothelial cells to form the stroma of the tumor, and numerous spaces, evidently dilated capillaries, which contained foreign-body giant-cells similar in appearance to those of the ordinary type of tumor. Whitman's case appears to be clinically similar to ours, as he states that it recurred twice after operation. These two cases, having similar clinical and histologic characteristics, form evidence that we are dealing here with a more malignant form of growth than the ordinary type of giant-cell tumor, requiring more extensive operation to ensure cure.

The unfortunate application of the term "sarcoma" to the ordinary giant-cell tumors of the jaws has led to much ruthless and unnecessary sacrifice of tissue in a part of the body in which a consideration of cosmetic results is secondary only to the life of the patient. There is no advantage in opening the face or excising half the jaw for the removal of these tumors when it is perfectly safe simply to shell out the growth from within the mouth without fear of recurrence. In the second or endothelial type, however, a more extensive operation is usually required. The nature of the growth can generally be recognized at operation, but if not, histologic examination will indicate whether or not further excision will be necessary.

REPORT OF CASES

CASE 1.—C. N., aged 37, was seen Jan. 5, 1914, with a growth on the gum of the lower jaw that he said had been there for sixteen years. It was slowly growing larger, but caused no pain. Examination showed a hard nodular swelling in the alveolar region of the lower jaw, extending from the left first premolar to the right lateral incisor tooth, several of the intervening teeth being displaced or loosened. Diagnosis: fibrous epulis. Operation consisted in extraction of teeth involved, and excision of growth and alveolar process from which it arose. Uneventful healing ensued. Histologic examination shows growth to be a fibroma (Fig. 2). There was slight evidence of myxomatous degeneration.

---

[6] Whitman: Jour. Med. Research, January, 1914, p. 465.

Case 2.—A. P., woman, aged 52. Patient first seen March 14, 1913. She had had no upper teeth for twenty years or more and wears a full set of artificial teeth. For at least ten years she has had a swelling on the right side of the upper jaw which never caused any pain, but is gradually growing larger and interferes with the fit of her plate. On the right side of the maxilla in the region of the alveolar ridge there was a smooth soft dark-red growth, about 1 inch long by ½ inch wide. The tumor was excised by Dr. M. H. Cryer, without any attempt at removal of the surrounding healthy tissue. Healing occurred in due course without any recurrence or other complications. Microscopic examination showed a covering of squamous epithelium, while the interior of the growth consisted of a fibrocellular stroma containing many foreign-body giant-cells (Fig. 3). Diagnosis: Giant-cell myeloma, benign type.

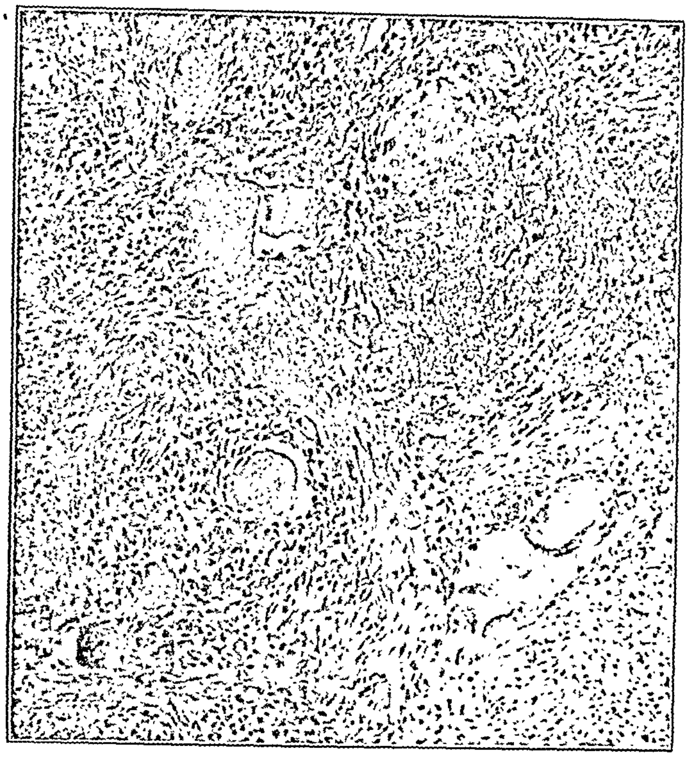

Fig. 3.—Histologic appearance of section from giant-cell myeloma, common type. Small masses of bone and cartilage seen.

Case 3.—M. W., woman, aged 22. Patient first seen Sept. 18, 1913, in association with Dr. R. H. D. Swing. For about three months she had noticed a gradually increasing painless swelling of the left side of the lower jaw, which caused displacement of teeth. Examination showed a smooth swelling of the gum on the left side of mandible extending from the first molar to the canine tooth. The teeth involved were sound but the premolars were somewhat displaced. The growth caused the internal and external alveolar plates to bulge, forming a thin shell of bone over it. The two premolar and canine teeth were removed together with their alveolar process and soft dark-red material was curetted out from the thin shell of the bone forming the body of the jaw at this point. The continuity of the bone was preserved. Slow but uneventful recovery ensued, and no signs of recurrence appeared after nine months. Several small masses of gritty material were scattered throughout the soft tissue, which proved to be small areas of bone and cartilage on microscopic examination. In other respects the tissue was similar to that found in Case 2. Diagnosis: Giant-cell myeloma, of benign type.

Case 4.—J. F., boy, aged 17. First seen Jan. 10, 1914. Patient stated that for about six weeks he had noticed, slightly to the left of the median line, a painless swelling of the lower jaw, which was increasing in size. Examination showed a spongy, non-tender growth, extending from the symphysis to the left first premolar. The growth extended upward about the necks of the teeth and below caused a bulging of the alveolar plates. The teeth were irregularly displaced by the tumor. The roentgenogram (Fig. 1) showed a light area in the alveolar process and body of the bone in the position corresponding to the growth. The operation by Dr. M. H. Cryer consisted of the removal of the teeth—from the right central incisor to the left first premolar—together with their alveolar process, and the shelling out of a mass of soft dark-red jelly-like material from the deeper portion of the bone. This tissue lay in a smooth cavity in the bone extending almost to the lower edge of the mandible, and appeared to be separated from the healthy bone by a sort of fibrous capsule. The cavity in the bone is slowly filling up, with no sign of recurrence of the growth. The tissue was histologically similar to that found in the two preceding cases. The outer portion of the tumor consisted of a condensation of the fibrocellular tissue, containing no giant-cells in this situation. Diagnosis: Giant-cell myeloma, benign type (Fig. 3).

Case 5.—R. D., boy, aged 9. Patient came to the clinic March 17, 1914, on account of a growth on the right side of the upper jaw. This growth had been noticed for about six months, and had been partially excised two or three times by a dentist, who took it for a simple hypertrophy of the gum caused by the irritation from decayed teeth. The growth was gradually increasing in size, but never caused any pain. Examination showed a dark-red, soft lobulated mass projecting from the right upper alveolar process at a position corresponding to the premolar teeth. The temporary molar teeth at this position had been lost, while the premolars were only partially erupted and covered by the growth. Operation March 20 by Dr. Cryer consisted in excision of the tumor, extraction of the two premolar teeth, and slight curetting of the underlying alveolar process. Uneventful recovery followed. Microscopic examination showed the tumor to be a giant-cell myeloma of the benign type.

Case 6.—W. T., man, aged 29. Patient was first seen Dec. 2, 1913, with a swelling of the right side of the upper jaw that he had noticed for about six months. He complained of practically no pain, but several teeth had loosened and been lost. Examination showed a dark-red enlargement of the right side of the upper jaw extending from the region of the canine to the second molar tooth. The growth was smooth, was not confined to the alveolar process, but caused a bulging over the hard palate almost to the median line. Operation by Dr. Cryer consisted in removal of the growth and bone from which it arose, through the mouth without opening the face. The tumor was found to extend into the maxillary sinus, which was curetted and packed. Micro-

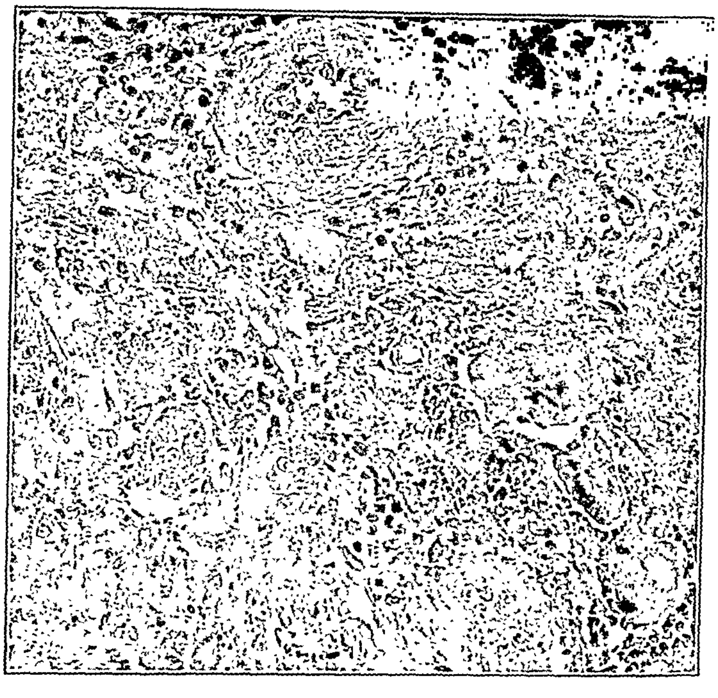

Fig. 4.—Section from giant-cell myeloma, endothelial type, showing proliferation of endothelial cells.

scopically the tumor was found to be a giant-cell endothelioma (Fig. 4) similar to that described by Whitman (see above). Feb. 23, 1914, a second operation became necessary owing to recurrence in the maxillary sinus and toward the median line of the palate. This was also performed without opening the face, a considerable portion of the palatal process of the maxilla being cut away, so that an opening was made in the hard palate between the mouth and the nose. Two weeks later a third small operation became necessary owing to a slight recurrence in the region of the maxillary tuberosity. At present the patient is apparently cured, and a prosthetic appliance will be made to close the defect in the palate caused by the operation.

SUMMARY

1. Epulic tumors may be classified as hard or fibrous, and soft or giant-cell.

2. The giant-cell tumors of the jaw bones fall into the two distinct classes: (*a*) the ordinary so-called giant-cell or myeloid sarcoma; (*b*) the giant-cell endothelioma, recently described by Whitman.

3. Tumors belonging to Type *a* have all the clinical characteristics of and may be regarded as benign tumors, and require only local removal of the new growth itself as in the case of other benign growths.

4. Tumors belonging to Type *b* are more malignant and should be treated accordingly by more extensive operation.

1623 Walnut Street.

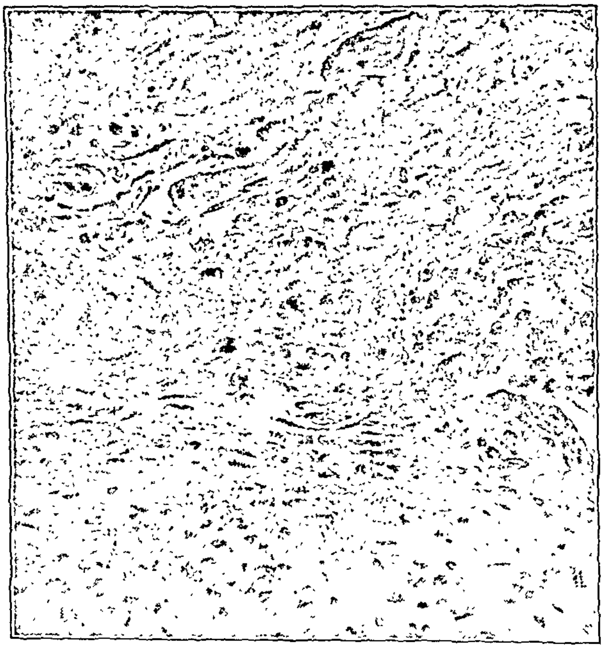

Fig. 5.—Section from giant-cell myeloma, endothelial type.

ABSTRACT OF DISCUSSION

Dr. R. P. Bay, Baltimore: I shall, in speaking of endothelial tumors, consider them not as epuli of the mouth, but as sarcomas. Some authors classify these tumors of the epulis variety as benign tumors which are histologically malignant; in other words, a sarcoma which is histologically malignant and yet benign clinically. As Dr. Ivy said, some cases of epulis and sarcoma around the gum are benign and some malignant; some shell out easily without much disfigurement or difficulty. In my experience it is impossible to apply any hard and fast rule in these cases. We consider, and probably we are right, that the older the individual the better the prognosis in cases of sarcoma occurring around the mouth, the same as we have in epithelioma and carcinoma. I have seen cases of sarcoma or epulis, and we may even see endothelial tumors occur practically at all ages from the infant to the advanced age of 68. We know absolutely nothing, so far as I know, of the cause of sarcoma or mesothelial tumors. It was once thought they were congenital. The most rapidly growing and the mostt advanced case I have had under observation was a case of giant-cell sarcoma which the pathologist thought was a typical simple epulis, occurring in a child 10 years of age. It was removed by methods that would be accepted as probably more extensive than ordinarily required, but it recurred very rapidly and in six or eight months a complete resection of the jaw was necessary. That was, according to our knowledge of the pathology of these cases, the variety that shells out very easily, though this case was a typical case of giant-cell sarcoma. The epulis occurring in old people usually starts from some irritation. They practically always start, I believe, from the periosteum coming out directly from between the teeth. It is useless to shell out these epuli without removing at least one or two teeth, or at least the tooth they are attached to. I assert that those who are teaching oral surgery and who come in contact with students, should advocate the complete and early removal of tumors and lumps of whatever character occurring around the gum. They can be, of course, innocent, and possibly the majority are, but they certainly can be as malignant or more so than any with which we have to deal. So that we should advocate the early removal of all growths coming from around the gum when the periosteum is injured or from some other cause. I believe also that after we remove the growth with the knife, the tissues should be cauterized with the electric cautery.

Dr. Virgil Loeb, St. Louis: How does Dr. Ivy classify the epuli which he calls typical angio-epithelioma?

Dr. M. I. Schamberg, New York: We frequently hear of radical operations being performed for so-called malignant growths about the mouth, and it has been my experience that these giant-cell sarcomas are in a measure inflammatory growths; they really assume the form of inflammatory tissue. In fact Dr. Bloodgood of Johns Hopkins has expressed a similar opinion with regard to the giant-cell variety of sarcoma. For that reason I am sorry that Dr. Ivy did not take up the subject from the etiologic point of view. These sarcomas are usually completely cured by simple removal. My experience conforms with that of those who have encountered these cases. I have run across few cases of giant-cell sarcoma that involved the maxillary sinus and which required further operation. I recently operated on one which appeared to involve the anterior wall of the antrum and caused the face to be quite prominent as high as the inner canthus of the eye, and after the operation there was quite a bit of surgical traumatic thickening of the periosteum which led me to believe I was going to have a recurrence. In that particular case the patient had been wearing some unhygenic bridgework in the mouth, with a cuspid tooth involved which I thought was the cause of this growth. After the removal of the tooth and the surrounding tissues by means of the curet followed by cauterization and packing the wound, the condition has completely subsided. Another feature of that case which led me to believe that it was largely inflammatory in origin, though under the microscope it showed the typical appearance of the giant-cell sarcoma, was that there were periodic swellings of the eye, with edema after the operation, which would give a clinical appearance of inflammatory growth. I believe, with Dr. Bloodgood, that these cases are of possible inflammatory origin and that these giant cells occur as the result of some form of chronic irritation. We know, too, that the true epulic growths occurring in and about the mouth, that spring from the periosteum, are inflammatory in origin, and are either produced by irritation of the teeth or by motion between two closely approximating teeth. The etiology of these growths is of great importance as it tends to bear out the clinical findings. I might also refer to a multilocular cyst of the jaw which was extensive, extending into the neck of the condyle of the jaw and in which almost the entire half of the jaw was involved, which I operated on some years ago, which under the microscope was thought to be malignant, but clinically the case ran a benign course. It became a very extensive growth with no involvement of the adjacent lymphatic glands, nor has there been any systemic effect, though the growth had assumed large proportions. In that case there has been almost complete regeneration of the side of the jaw and ramus.

Dr. F. B. Moorehead, Chicago: Histogenetically, there are three distinct varieties of fibroma found in the mouth—from the gum, from the periosteum and from the peridental membrane. The difficult feature is to determine the parent cell and be guided entirely by that in the removal of these growths. There are some sharply defined clinical characteristics that will lead to a conclusion as to whether they come from connective tissue in the gum, in the peridental membrane or in the periosteum. It is perfectly obvious that, if the fibroma has originated in the peridental membrane, the simple enucleation, so-called, is going to fail and the removal of the tooth in that case is always indicated. If, on the other hand, it originates in the periosteum, then an incision down to and including the periosteum is all that is necessary. This is an important point. One striking thing about this whole mesothelial group is that the malignancy has a definite relation to the size of the element. The smaller the element, the more malignant, and when we have the small round-cell type it is an extremely malignant form. Some run a benign course throughout, while others are malignant from the beginning. Others begin as benign tumors and later degenerate into malignant tumors. We should look with suspicion, therefore, on all connective-tissue growths found in the mouth. I wish we might get away from the term "epulis." It means nothing and is frequently misleading.

Dr. C. K. Teter, Cleveland: One important point is the accuracy of the report from the pathologist. Anybody doing much of this work gets into deep water sometimes if he accepts the report of the pathologist as final and carries out his work along that line, as two cases I will speak of will show. One case which occurred about eight years ago was that of a small tumor on the side of the upper jaw, located near the upper third molar, and which turned out to be a fibroma. After the tumor was taken out, which was easily done, it was sent to the pathologist and the report came back to me that it was a giant-cell sarcoma. I felt it my duty to notify these people and to tell them that a far more radical operation should be done. They did not see fit to have the operation, and eight years have elapsed without a recurrence. That family has been quite indignant with me because I suggested a radical operation. Two years ago, I had an old gentleman over 80, who had a growth in his upper jaw which entirely filled the antrum and which shelled out easily. It was a spongy growth. I sent it to the pathologist and the report came back to me that it was a simple papilloma. I did not think anything further was necessary if that was the case, as the tumor came out practically intact. This man died from a sarcoma in about three months. I simply call attention to the fact that it is important to have an accurate pathologic examination.

Dr. T. L. Gilmer, Chicago: I would second Dr. Moorehead's remarks relative to the name, epulis. It is misleading and conveys a wrong impression, since the growths under consideration do not spring from the gum, as would be indicated by the name. I believe, with Dr. Schamberg, that the so-called epulis arises from irritations in most instances. If we examine the teeth closely, which these tumors approximate, a bit of calculus or a sharp edge on a broken or decayed tooth or root is generally found, or there are pockets about the teeth in which food or other debris has lodged. Those growths, sometimes called epulis, originating within the bone, are of a different origin and are more likely to be malignant. I have noticed that the tumors under discussion are malignant in proportion as they grow rapidly or slowly, those growing the most rapidly being the most malignant. Tumors of slow growth having the appearance of a fibroma, are most likely to be, histologically, giant-cell sarcomas. If they grow quickly and are soft and more vascular, they are more likely a different type of sarcoma, that is of the spindle or round-cell variety and are always malignant, while the giant-cell type is not usually so. With regard to radical operations for the removal of these growths, I read a paper some years ago in this section relative to radical operations for removal of tumors of the mandible. My belief was, and still is, that unless there is positive evidence microscopically that a tumor of the mandible is a rapidly growing malignant growth, a less radical operation should be first done and the case watched, rather than to sacrifice a large section of the jaw, which in the past has been done too frequently. I would not, however, simply snip off the growth, I would cut away all bone up to what appears to be immune area.

Dr. John S. Marshall, Berkeley, Cal.: I have been much edified by the discussion of this subject. I remember when a paper of this character would have fallen flat before a dental society; it would not have been discussed at all because nobody would have been capable of discussing it, but now more than half a dozen young men are capable of discussing this question in all of its aspects. This is particularly gratifying to me because I feel that I have had some little part in stimulating the young men to take up the subject of oral surgery. In my teaching work I have endeavored to impress on the minds of the young dentists in my classes that this was their particular field and should not be turned over to the general surgeon. Most of our young men have been afraid to tackle these cases, largely because the schools do not give the proper training in anatomy, histology, pathology and histopathology. The schools, however, have improved very much in that line in the last few years, and I am greatly pleased to see so much interest taken in this subject in this society, because it has been the pet subject of my professional life. When I first started out to study oral surgery, thirty-five years ago, about the only man who was doing anything was Dr. Garretson of Philadelphia, who, by the way, was the Nestor of oral surgery in this country. He said, in his talk on tumors, "If you cannot easily explain the character of a tumor as being positively malignant, treat it as a malignant tumor anyway and remove it," and that has been my practice. I do not temporize with them. If I cannot explain their character, I treat them as malignant and take them out, and I know positively that I have saved many lives by doing this. The application of irritants to a carcinoma or epithelioma is much like touching a match to the material of a bonfire—they go very quickly. There is nothing that will eradicate them so well and so surely as the knife, provided the operation is made before the glandular structures have become involved.

Dr. R. H. Ivy, Philadelphia: With regard to the etiology of these tumors, I have seen cases in which there was no indication of any inflammation or irritation, and others, on the other hand, which presented marked signs of inflammatory irritation, so that we cannot say definitely that these growths are stimulated by inflammatory conditions. In speaking of "shelling out" the tumors in treatment, I do not mean to avoid extracting teeth or removing bone from which the tumors may spring; I mean to extract the teeth involved, then simply enucleate the tumor itself, taking away as little of the good bone as possible. Again, I think we can generally diagnose the variety of the tumor by whether it is hard or soft. The great majority of fibromas are hard, while the giant-cell tumors are usually soft. Cases of fibroma may be found in mouths that are in a filthy condition, and I have seen the soft variety of epulis in clean mouths. In the pathologic diagnosis of these cases I believe that the surgeon or somebody connected with his clinic should follow them to the laboratory and confer with the pathologist. In that way I think there will be few mistakes and we will have few conflicting reports from the laboratory. With regard to the term angioma, in classifying tumors, it depends on the amount of vascular tissue found in them. If we find a fibroma which contains a large amount of vascular tissue we might call it an angiofibroma.

Exact Observation the Physician's Prime Essential.—There is one quality the possession of which is the supreme need of the physician, without which he is as unfit and useless as a tone-deaf musician or a color-blind painter; that is, the faculty of exact observation.—Minot.

THE RADICAL REMOVAL OF THE VERUMONTANUM

WITH NOTES ON PATHOLOGY*

A. G. RYTINA, A.B., M.D.
BALTIMORE

Since the advent of urethroscopy, diseases of the verumontanum have been of interest to the genito-urinary specialist, and a large and varied number of sexual, urinary and reflex disturbances have been described as caused by pathologic conditions in this organ. As far back as 1879, we find Grünfeldt, in the first book which appeared on urethroscopy, devoting a large chapter to diseases of the verumontanum, and discussing methods of therapy. In 1882 we find Burckhardt recommending the employment of silver nitrate and the thermocautery in combating affections of this organ. Following the appearance of these articles, we find in the literature quite a few dissertations dealing with this subject, but nothing of material advance has been made, unless it be the suggestion of some of our American authors, that perineal section and curettage of the verumontanum be employed in those cases that do not respond to the application of silver nitrate, the thermocautery, etc.

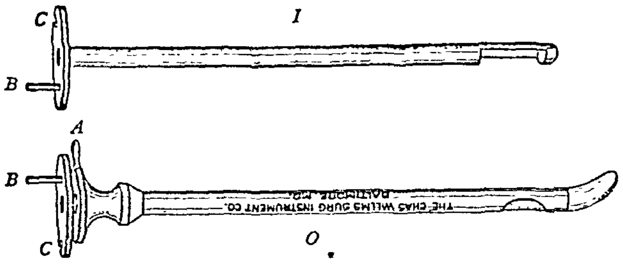

Fig. 1.—Endoscope.

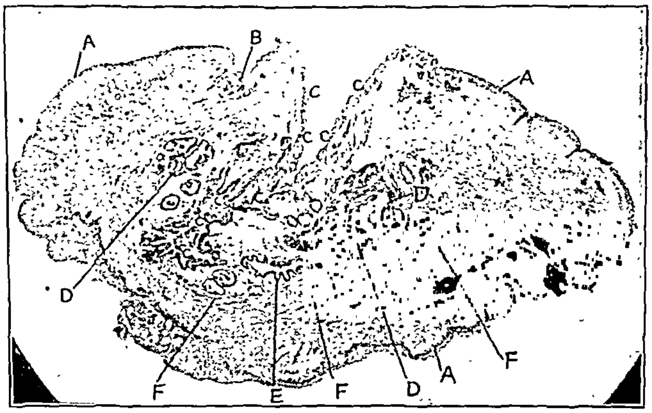

Fig. 2.—Section of normal verumontanum showing course and structure of sinus pocularis: *a*, mucous membrane; *b*, pit formation; *c*, sinus pocularis; *d*, central group of glands, some showing infoldings; *e*, duct; *f*, capsule; *g*, stroma.

As the histology and pathology of the verumonatanum has been almost an entirely neglected field, the therapeutic results obtained are based only on empiricism, and therefore liable to error. That clinical improvement often follows applications to this organ cannot be gainsaid, yet it has never been accurately determined whether the improvement is due to a psychic influence, to a specific action on the verumontanum or to the general effect on the whole posterior urethra. That many authorities believe that the favorable action is due to the application to the verumontanum itself is indicated by their dictum that the application be strictly confined to this organ. On account of the lack of scientific proof, I have never been firmly convinced of the important rôle of the diseased verumontanum in causing so many untoward symptoms, and have been surprised that such sequelae as cicatricial obliteration of the ejaculatory ducts, with resulting sterility or painful ejaculation, have not been of more frequent occurrence after the use of the thermocautery or repeated applications of strong silver nitrate. Furthermore, other complications, such as urethritis, cystitis, prostatic abscess, severe urethral hemorrhage with retention of urine, epididymitis, as well as the painfulness of the applications and the necessity of repetitions in most cases, have led me to attempt an improvement on the present mode of therapy. By means of a technic to be described presently, the verumontanum can be removed with much less risk of the complications or sequelae described above and with much less pain and reactive symptoms that ordinarily follow a silver nitrate application. Furthermore, the operation is radical, and in allowing the removal of the almost intact verumontanum, enables us to make accurate pathologic studies, with the result that a more rational interpretation of the symptomatology and therapy may be anticipated. Of course, the operation should be carried out only in selected cases.

DESCRIPTION OF TECHNIC OF OPERATION

The instrument is composed of two parts, *O* and *I* (Fig. 1). *O* is nothing but an ordinary curved posterior endoscope, having a large window on the convex surface near the beginning of the beak. The caliber is 28 F. *I* is a straight hollow tube which is also fenestrated. The edges of the latter are made of steel and well sharpened, the latter being an important particular. When *I* is introduced into *O* and the two guide-posts *A* and *B* are at right angles, the instrument is closed and *I* acts as an obturator. The instrument is introduced in the posterior urethra and *I* is rotated 180 degrees, or until the groove *C* fits into *A*. The instrument is now open. An ordinary Young's endoscopic light is now attached and the verumontanum located by pushing the instrument in or out, as the case may be. The structure is recognized by its shape, color and particularly by the opening of the sinus pocularis. In some cases it requires a little experience before one can differentiate between the verumontanum and the mucous membrane bulging in the lumen of the instrument. An application of epinephrin and cocain may now be applied, but this is not absolutely necessary. The light is now detached and the instrument rotated slightly to the patient's right, the ocular end elevated and held firmly. *I* is now rotated from the 6 o'clock aspect from left to right, stopping at a point a little beyond the 12 o'clock aspect. By rotating the instrument in the direction indicated, the knife-blade first encircles the verumontanum and only begins to cut when it reaches about the 11:30 o'clock aspect. The successful excision is indicated by a sense of slight resistance imparted to the finger. Following the excision, the inner tube containing the verumontanum is withdrawn and an application of cocain and epinephrin is made through the outer tube, although I have lately discarded the latter procedure. If desired, the entire instrument can be at once removed. However, one should be certain that the cut has been clean and no mucous membrane attached by rotating the instrument. The patient is then put on hexamethylenamin for a few days. Verumontana that are adherent to the urethral walls, or that are highly edematous, may slip out of the window during the process of rotation. This difficulty can be lessened by introducing a finger into the rectum between the two lobes of the prostate and in that way aid in making less mobile the verumontanum and posterior urethra. The pain following the operation is less than follows a strong silver nitrate application and the hemorrhage is never alarming, and ceases in a few minutes. Reactive symptoms, such as pain and hematuria, disappear in from twenty-four to forty-eight hours. We have tried this operation about eighteen times and the only complication we have had, has been one case of acute epididymitis. We have satisfied ourselves of the patency of the ejaculatory ducts by demonstrating spermatozoa in the semen. Colliculectomy does not affect the patient's sexual appetite. Following the removal of the verumontanum, endoscopy of the posterior urethra shows a slight elevation of the mucous membrane in the position of the former verumontanum and one or both ejaculatory ducts are in most cases visible.

---

* From the Departments of Genito-Urinary Surgery of the College of Physicians and Surgeons and the Johns Hopkins Hospital.

* Read before the Section on Genito-Urinary Diseases at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

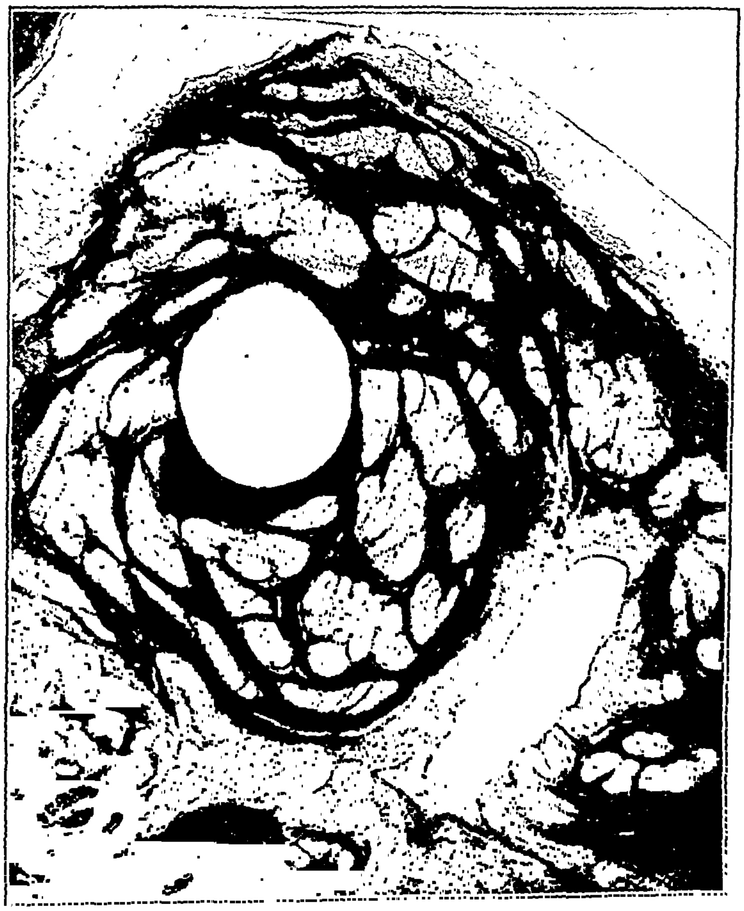

Fig. 3.—Section of verumontanum showing elastic tissue formation. Photograph includes central glandular portion and only small part of stroma portion. Darkened areas represent elastic tissue. Note how it enters into formation of walls of acini and the stalks of the infolding processes.

I am not prepared at this time to speak of the clinical value of the operation, but prefer to discuss the anatomy, histology and pathology of the verumontanum, which the excisions afforded me. Suffice to say that unless the therapeutic results are due to a specific action of the measures employed, or the general action on the whole posterior urethra, the operation must at least emulate, if it does not excel them. I am free to confess, however, my belief that the beneficent results in many cases are due in no small measure to the coincident action on the whole posterior urethra, a view which is not shared by most observers.

ANATOMY

I have examined a large number of text-books on embryology, histology, anatomy, pathology and genito-urinary surgery and it is surprising what a dearth there is on the subject of the verumontanum. Practically all repeat that the verumontanum is a rounded elevation situated on the floor of the posterior urethra, having opening on its lower front walls the ejaculatory ducts and on its upper anterior surface the sinus pocularis. Some erroneously assert that the ejaculatory ducts always open in the sinus pocularis. The latter in man is a rare occurrence. Nowhere have I seen its histology described in detail. This I propose to do. The gross appearance of the verumontanum shows the color a pale pink, lighter in hue than the surrounding mucous membrane of the urethra. It is rounded or oval in shape, excepting the base, which is more flat. The sinus pocularis may be represented by a small rounded opening or as a mere slit. The ejaculatory ducts are difficult to see. Its consistence is fairly firm and judged from the surface, would seem to be more or less homogeneous, but on examining the base, a truer knowledge of its structure is at once evident. Here one notes that the verumontanum is composed of two distinct structures separated by a dense, pearly-white, circular capsule. The inner or central portion comprises about one-fourth to one-third the whole, has a yellowish color, a loose, spongy, lobulated character and projects over the rest of the base of the organ. In its immediate center is a minute aperture. A fine wire or probe is easily admitted, extends through and comes out at the opening of the sinus pocularis above. The outer or peripheral portion comprises about two-thirds or three-fourths of the whole, is grayish pink in color, its texture fine, close and more or less homogeneous.

HISTOLOGY

The microscope readily enables us to differentiate the verumontanum into a central glandular portion and a peripheral stromal portion. The surface is covered by a many-layered, stratified, squamous epithelium, similar to that seen on the surface mucous membrane of the posterior urethra. Below this, one sees a layer of subepithelial connective tissue stroma. Deeper down in the central portion, one encounters groups of glands which show numerous intra-acinous proliferations. These infoldings are composed generally of several layers of epithelial cells, which may be of the simple cuboidal, columnar or squamous type. At times one can see the infoldings of a stratified type in one portion of the acinus while another will exhibit the cells composed of a simple, cuboidal epithelium. At times the infoldings are composed of a solid mass of epithelial cells. More often one can see a fine supporting stalk. Many of the acini seem to be dilated. No corpora amylacea are seen and the lumen of the glands seems to be empty. The outer, or the peripheral portion, is composed largely of normal-looking fibrous tissue stroma containing here and there an occasional glandular acinus, which may show the same infoldings already described. Several observers have removed polypi from the verumontanum, which had the same microscopic appearance as the foregoing and which they termed "glandular polypi." It is possible that they were describing the verumontanum itself. The capsule is composed of dense, circular bands of fibrous and elastic tissue. By special staining methods, we were able to show that the verumontanum both in the glandular and stroma portions, contains much elastic tissue (Fig. 3). This, however, varies in the different specimens. It is arranged in long wavy strands, and is fairly rich in the capsular portion. From here, one can see it extending into and forming part of the intra-acinous stroma, the walls of the acini and the stalks of the infoldings. Fibrous tissue, of course, is the predominating stromal element. The verumontanum is poor in involuntary muscle fibers, not especially rich in nerves, but plentifully supplied with blood-vessels and lymphatics. This microscopic picture somewhat resembles prostatic hypertrophy. The differentiation is made by the fewer acini, the lessened dilation and the lessened infoldings of the acini and the greater amount of intra-acinous stroma seen in the verumontanum.

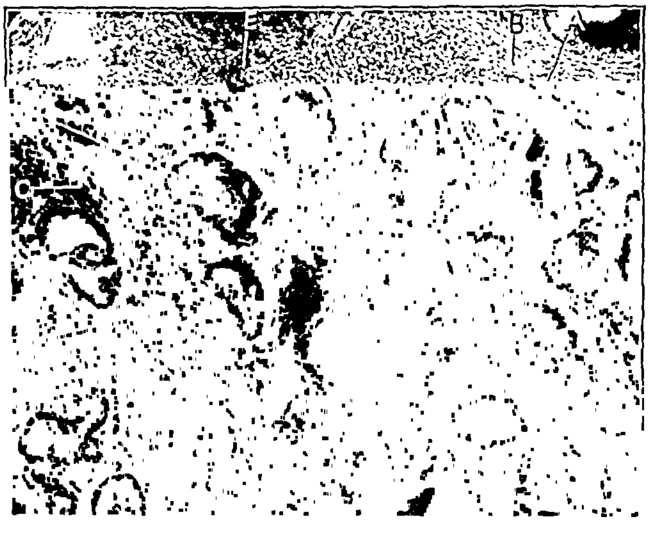

Fig. 4.—Section through an infected verumontanum. Infection is limited to left half; right half is normal: *a*, normal acinus showing infoldings, suggests prostatic hypertrophy; *b*, normal stroma; *c*, periacinous infiltration with round cells; *d*, normal acinus replaced by round-cell infiltration; *e*, infected stroma.

SINUS POCULARIS

Most text-books simply describe the sinus pocularis as a rounded or slit-like opening on the anterior summit of the verumontanum. Burckhardt mentions that it courses through the verumontanum and then blindly ends in the substance of the prostate. It is developed from the lowermost ends of the mullerian ducts and is therefore analogous to the female uterus and vagina, on which account it has been called the uterinus masculinus. Our studies show that the sinus pocularis (Fig. 2) is a long canal lined by a many-layered squamous epithelium, and by serial sections we have been able to demonstrate that it ends by a complicated system of invagination processes. They are also lined by the same type of epithelium and suggest glandular organs, but are probably only secreting surfaces. It is easy to see how favorable this structure is for retention products and suggests difficulty in eradicating infection. Surrounding the sinus pocularis are the central group of glands already described.

PATHOLOGY

The only type of pathologic verumontanum that we have been able to study thus far has been that due to infection. We have had several such cases, but they nearly all show the same picture (Fig. 4), namely, a submucous and a periacinous infiltration of round cells, among which one can see an occasional pus-cell. In some places round-cell infiltration may be so marked that it will completely replace the position of a former acinus. At times one can see in the interior of the acinus round-cells, pus-cells or desquamated epithelial cells. Occasionally red blood-cells may be seen, the result of trauma. We have sections which show infection traveling down the length of the sinus pocularis into the invaginations below, showing the necessity of injecting the canal, as first suggested by Luys and later independently by Geraghty. Indeed, we believe that researches that we are now carrying out will show that the sinus pocularis is often the most important factor in keeping up infection in the verumontanum and that the surface appearance of the latter indicates the pathologic condition in the utricle below, as an ulcerated ureter mouth reflects kidney tuberculosis above. Let me cite a case to illustrate this point:

W. S., complaining many months on account of frequent nocturnal emissions: Endoscopy shows a highly inflamed verumontanum covered by many granulations. Several applications of caustic to the verumontanum brought no relief in symptoms or improvement in the appearance of the organ. Once following mere endoscopy and another time after the application of caustic, patient had severe urethrorrhagia with retention of urine. During endoscopy, March 30, 1914, the edge of the tube was pressed against the verumontanum and a drop of thick pus exuded from the utricle. Injections by means of Geraghty's syringe were now given and following the second or third injection, the patient's symptom of emissions disappeared and verumontanum assumed a normal appearance. He is still being treated for his chronic urethritis.

Finally, it seems to us that discharges in the urethra are perpetuated or rekindled by infection in these glandular structures, and a more wide recognition of this fact will be followed by an increased percentage of chronic gonorrhea cures.

CONCLUSIONS

1. Colliculectomy is a simple operation for removal of the verumontanum. It is less liable to untoward complications and sequelae than strong applications of silver nitrate or the thermocautery.
2. The study of the pathology of the verumontanum is made easy, in consequence of which a therapy will be devised that will be based on science, rather than on empiricism.
3. Surface applications of mild antiseptic solutions *seem to be irrational.* Strong penetrative cauterant substances may have great therapeutic value in curing infections, but may do more harm than good, on account of the production of untoward complications or sequelae.
4. A straight-beaked colliculectotome lends itself to removal of vegetations and polypi from any part of the anterior urethra.

THE ENDOSCOPIC TREATMENT OF NOCTURNAL POLLUTIONS*

ALEXANDER RANDALL, M.A., M.D.
PHILADELPHIA

With the introduction of a new procedure for the purpose of examination and treatment, there occurs of necessity a period of time before its recognition becomes general and its utility established. After this neophytic period has been successfully passed and the new procedure has established its worth and the medical profession has accepted its new aid, it becomes incumbent on those interested to separate the component parts and special fields of utility of the newcomer and to study in such smaller groups the various advantages and finer details, so that in the end the composite whole stands out the more clearly by reason of the sharp details of its individual features.

This is true at present of the value and use of the endoscope, now securely established as to its utility in examination and treatment, and it behooves us, the urologists, to group the cases, such as chronic posterior urethritis, sexual neuroses and abnormalities, polyps and neoplasms, diverticula, chancres, chancroids and herpes, etc., so as to allow of separate intensive study and analysis, by means of which we may hope to classify the findings, to establish the pathology, and to perfect the treatment by the correlated results.

With this in view I have endeavored to present here a brief survey of my experience in handling cases of nocturnal pollutions by means of the endoscope.

In speaking of nocturnal pollutions or emissions, the question always arises: What constitutes a digression from the normal? This is purely an academic question on which many varying views are held. Suffice it, at this time, to state that I am considering the condition a pathologic one only (*a*), when the pollutions occur more often than twice a week over a period of two months or more, especially when they occur on succeeding nights or when twice or more during one night, or (*b*), when the pollutions leave the patient mentally depressed or physically fatigued during the morning of the succeeding day. I feel that this is a most generous limit.

It has been my universal experience in handling these cases to find, on endoscopic examination of the posterior urethra, varying degrees of pathologic changes in the walls either of the urethra, or more frequently of the colliculus itself.

At times the walls of the posterior urethra are but slightly excoriated with areas or streaks of a raw redness, often covered with superficial granulations that bleed on touch. This comparatively mild irritative reaction is less frequently seen than a general sodden engorgement of the walls, which appear mossy, dark red, redundant, and fold into the end of the urethroscope. Twice I have seen a general varicose condition, which one might call hemorrhoidal, in which the turgescence of the vessels caused the walls to appear actually blue—a venous stasis.

Even more pronounced changes are found involving the colliculus, which is, likewise, the most frequent point diseased. It is found enlarged to double its size, hyperemic, succulent, and especially tender to the touch. At times it has a raspberry appearance, covered with gross granulations; at other times an exudate covers all or part of it. Actual ulceration, by which I mean a localized circumscribed area of erosion, though rare, is occasionally seen. Polyps, retention cysts of either the utricle, the ejaculatory or prostatic duct orifices, have been recorded. And here let me call attention to a condition rather often seen, whose significance I know not, nor have I seen reference to it elsewhere, and that is that in some cases one sees on the colliculus smaller areas of darker red tissue which appear to a certain extent translucent, and you seem to see deeper into the tissue; these areas are flush with the surface but not covered with the normal mucous membrane; they are not ulcerations and have no exudate. They are especially resistant to cauterization and often show remarkably rapid changes in growth. From what tissue I have been able to study histologically, these areas appear to be formed of glandular hyperplasia, and whether or not they have any connection with the occurrence of subjective symptoms I have not, as yet, been able to prove to my complete satisfaction. The question of course immediately arises, Are these marked changes, found in the posterior urethra on endoscopic examination in cases of frequent nocturnal pollutions, the cause or the effect of the emissions?

Sexual function, like other physiologic functions during the period of adolescence, grows with the excessive use of it, and when we search the histories of these cases it is rare indeed that we are not able to find some antecedent, in the form of either a sexual misdemeanor or some irritative infection, to account for the urethroscopic findings and one that will bear on the etiology of the condition.

Twenty-one per cent. of my cases are in a class in which there has been no antecedent history of any infectious urethral disease. Practically every one of these patients has at some period of his life been an excessive masturbator. The cases of this group illustrate repeatedly the gradual creation of a congestion of the sexual apparatus through repeated insults, until permanent pathologic changes, such as cited above, have developed. Practically every one confessed to having performed the act every day over a period of one or more years, while some have been such chronic habitués that they have repeated it as long as erection was possible.

To be sure, in these non-infectious cases, while the pollutions are the effect of the pathologic changes in the posterior urethra, at the same time, they are both indirectly the effect of an excessive libido, and follow some form of excessive sexual indulgence as an antecedent cause. But it is through the increasing and prolonged stimulation of the genital nerves and especially the nerves to the blood-vessels, combined with the mechanical insults, that a static catarrhal condition develops. The described proliferative pathologic processes develop and spread, and with this there appears the common source for both the pollutions and the continuance of an excessive sexual appetite. The sexual misdemeanor, the result of the unsatisfied libido, is the cause of the pathologic changes in their beginning, but when once established, these changes in turn artificially stimulate the libido and either become overpowering to even the strongest will-power, or, if the habit is actually stopped, manifest themselves in the form of frequent seminal emissions on the slightest provocation. Allow me to cite such a case:

R. F. started masturbation early in life and practiced it regularly twice a day, night and morning, for three years. He then desisted and emissions began and soon increased in frequency, until they now occur always twice a week and often to such a degree that, as during the last week, he had five in three consecutive nights. The mildest social pleasures are associated with ejaculation. Even a rub-down after a boxing bout in the gymnasium brings on an erection and a subsequent ejaculation. He never had a urethritis and sexual intercourse is impossible on account of premature ejaculation. On endoscopy the colliculus was found to be so swollen that only part of it could be seen at a time. It was dark red and its surface roughened and appeared to be covered with fine granulations. The urethral walls were markedly engorged. He received three applications of silver nitrate at weekly intervals, and the pollutions diminished in frequency to once in two weeks, and after two months' rest and observation with the continuance of such improvement the patient was discharged from treatment.

---

* Read before the Section on Genito-Urinary Diseases at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

Another case with somewhat different history is that of J. C., aged 17, who masturbated in excess for several years, often repeating the orgasm three or more times in immediate succession. He stopped the practice eighteen months ago. At first pollutions would occur once in a month and have gradually increased in frequency until now they occur five times a week, often on succeeding nights, and leave the patient in the morning fatigued and with a dull pain across the small of the back. He thinks that once he noticed blood in the seminal ejaculation. He has never attempted intercourse. On endoscopy there was found on the tip of the engorged colliculus one of the areas of glandular hyperplasia, to which I referred above, appearing as a soft angiomatous spot, of a dark purple color, and a little to the left of the mid-line. It was severely cauterized. After three applications of the cautery by means of the endoscope at weekly intervals the patient reported that he had had no emissions in the passed two weeks and was feeling perfectly well. His posterior urethra was normal and he was discharged.

I have attempted to show how such misdemeanors cause an atonic congestion of the delicate tissues of the erectile colliculus and of the entire prostatic region of the urethra. When once such a condition is established, this pathologic area forms but one segment of a vicious sexual cycle. Should the habit be broken off, as most of these patients attempt to break it, when with years discretion develops, the cycle continues, that is, an irritated and congested posterior urethra, giving stimuli to the sexual centers, causing erection, then more stimuli and ejaculation. The one place to attack and break such a cycle is to cure the region of primary injury in the posterior urethra.

A second and larger group of patients (42.8 per cent.) have given a history of an antecedent gonorrheal urethritis. Although possibly it is not quite fair to group all these infectious cases together, simply because of the past history, yet the changes that one sees in the posterior urethra under such conditions can be told only with difficulty from those of the previous group, and it is often the accuracy of the history as given that makes this type of case to be classified as a postgonorrheal complication. Exudate in the posterior urethra in my experience speaks for infection and is the only sure sign that is telltale of a previous specific urethritis. Often the history is as definite as that of W. H. D., who acquired his initial specific urethritis in February, 1913. It became posterior and was complicated by a right-sided epididymitis. In May the last traces of the discharge disappeared. In August the increasing frequency of nocturnal pollutions attracted his attention for, as before he would have only one in every three or four weeks, since the subsidence of his urethritis, they have gradually increased until now he has three or four a week, often twice a night. Insomnia, lassitude, pains in the hips and back are troublesome subjective symptoms. The urethroscope demonstrated an exquisitely tender colliculus, two or three times normal in size, thickened, engorged, dull and tense, non-ulcerated. Five endoscopic applications of silver nitrate, with lavage of the utricle, at weekly intervals gave prompt results and the patient was given one month's rest. At the end of that period he was sleeping better and had had but one pollution during the month; the pains were all gone. A second report four months later showed that he was perfectly well and normal in all respects.

Three of my patients presented polyps of the posterior urethra. One denied having had gonorrhea, in the second case it was not stated, while the third was complicated by a chronic posterior urethritis. The pollutions have been cured in all by the removal of the polyp and in the third by the subsequent cure of the urethritis.

Local treatment of these pathologic changes has been carried on through an open-air endoscope. Various solutions have been tried out, including zinc and copper sulphate, tannin, argyrol, protargol, iodin, trichloracetic acid, and various combinations that have been found efficacious in the treatment of lesion of the mucous membrane elsewhere about the body. When all is said and you really want work done, however, there is but one universally useful preparation, and invariably, one falls back on different strengths of silver nitrate. I find the 10, 20 and 50 per cent. solutions the best for superficial changes and use the crystal only when I want actually to destroy tissue. One should always remember, when using solutions in the posterior urethra, that after applying the medicament and giving it the necessary time to act, the field of operation should be completely dried with a cotton swab, and if this precaution be observed the patient is spared a great deal of discomfort. Electricity in its various forms has not in my hands given any satisfactory results.

In offering this brief survey it has not been my purpose to convey the idea that every case of frequent nocturnal pollutions is promptly and permanently cured by endoscopic treatment. My hearers are too familiar with the problems of our work to believe such a thing were it even intended. That remarkably beneficial results are obtainable in decidedly more than the majority of cases, however, has been my experience. I know of no distinguishing feature of any individual patient, or history, whereby one can prophesy that this patient he can cure and that one not, although it seems that often the most brilliant results are obtained in the most aggravated cases. Another feature is worthy of remark and that is that frequently the greatest benefit is demonstrated a month or more after all treatment is stopped. This latter feature has rendered it impossible for me to tabulate my results accurately, where a large number of the patients have been derived from dispensary practice with the usual inability to trace the subsequent history of such patients satisfactorily at an interval of six months or a year or more, after discharge. Those who have been under private observation, however, and those who have responded to inquiry, or have returned for observation, make me sanguine that the results in a large majority have been most happy.

Professional Building.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. RYTINA AND RANDALL

Dr. H. L. Leiter, Syracuse, N. Y.: In cases with doubtful history if bacteriologic and serologic examinations are made, we will occasionally obtain favorable results. With regard to cauterization of the posterior urethra, I think we should use some discrimination as to what cautery we use. If the whole lining of the prostatic urethra is affected, the solutions of silver nitrate may be effective, but when there are small isolated spots, in my experience, fulguration has worked very well. The photomicrograph of the sinus pocularis illustrates that very well. One could not expect a silver-nitrate solution to get down into that sinus very far, nor the silver stick, but one could put the fulguration wire down there and perhaps the treatment would be more efficacious. I have heard of accidents with fulguration in the prostatic urethra, but in my experience I have had none. Have any of the other members had any accidents with it? Has Dr. Rytina found any process other than inflammatory?

Dr. J. D. Barney, Boston: Dr. Rytina has made a valuable contribution to our knowledge of the organs at the neck of the bladder. The pictures which he showed were strikingly like those of the seminal vesicle, the ampulla of the vas, and the prostate. When we realize how very complex and how minute are the acini in which a gonorrheal infection can lodge, we will find easier the explanation of the difficulties that we have in curing our cases of chronic gonorrhea. When we realize that these regions resemble a sponge, and how difficult it is to get the sand out of a new sponge, we will understand that long-continued treatment by silver nitrate or massage or fulguration is the only way in which such patients can be cured. The verumontanum is closely similar in structure to the vesicles and the ampulla of the vas, as I have been able to show by pathologic studies of these organs.

Dr. F. W. Robbins, Detroit: Removal of the verumontanum appeals to us as being radical; we do not hear very much about the dangers that may result from it. Dr. Rytina spoke of the blood-supply of the verumontanum. I have had one or two experiences that assured me that the blood-supply is a factor that should be taken into consideration, and we must also remember that these urethras are septic and manipulation may lead to epididymitis. I had one case in which epididymitis followed removal of the verumontanum. A patient had been suffering much with various nervous phenomena that I attributed to the possible trouble with the verumontanum. The man had had a suprapubic cystotomy (the surgeon thereby hoping to get at the condition through the bladder) as well as milder forms of treatment at many hands. This man had a verumontanum that through the urethroscope appeared to be large, pale and leathery, much like the appearance of the vagina of a prostitute, that has continually been burned with mercuric chlorid solution. This man had as a result of the various diseases an atrophied testis on one side. When I saw the veru, thinking that I could do nothing further with it, I cut it off with a small pair of scissors. Following its removal he went home in good condition, but the next day I found a large amount of blood in his bladder. After breaking up the clots with a large sound, they were readily evacuated. The interesting point, to my mind, was not that he had, following the traumatism, a slight epididymitis on the healthy side, but his neurotic condition, when he felt that the doctor had done the worst thing possible for him in making him absolutely sterile by producing an epididymitis on his only healthy side, the other testis being valueless. The amount of hemorrhage after this operation was a matter of considerable moment, and if we can accomplish the same purpose with the high-frequency current as we can with a cutting instrument, it will be an advantage.

Dr. Herman L. Kretschmer, Chicago: It is not quite clear to me just when we should excise or remove these vera, and when we should be satisfied with local applications. Will Dr. Rytina tell of the condition of the prostate in the patient with infected verumontanum?

Dr. Louis E. Schmidt, Chicago: These chronically infected utricles persist for a long time. Occasionally during the course of such a chronic urethral infection of the adnexa one sees a so-called prostatic abscess arise. I believe that a great many so-called prostatic abscesses are nothing more nor less than pseudo-abscesses of the utricles. These abscesses may reach an enormous size, the fluctuation can easily be felt by rectum, and if, in these cases, we watch the increase of the fluctuating area, we will note that the fluctuation is always in the median line. I am quite certain that these pseudo-abscesses of the utricles are frequently mistaken for prostatic abscesses. Therefore I think it is well always to examine any chronic posterior urethral infection and to treat these conditions, because the possibility of abscess formation is constantly present.

Dr. E. L. Keyes, Jr., New York: Dr. Rytina has shown us pathologic specimens exhibiting changes in the utricle. He would be the first to say that he could show us similar changes in other urethral glands. The beauty of the dilatation treatment of chronic urethritis, as contrasted with too much dependence on treatment through the urethroscope, is that the effect of pressure extended over a considerable portion or over the whole urethra is likely to do more good in most instances of chronic urethritis than the especial attention to one set of glands which happen to be more visibly diseased than others. With regard to the remarks of Dr. Schmidt on prostatic abscess, the pathologic investigations of the late Dr. Samuel Alexander, which I have been able to verify, are calculated to show that, probably in the great majority of instances, prostatic abscess begins as a miliary suppuration throughout one or other of the lateral lobes of the prostate itself.

Dr. John A. Hawkins, Pittsburgh: Dr. Rytina spoke of the possibility of epididymitis following applications to the verumontanum. In my experience epididymitis rarely follows treatment in the neighborhood of the verumontanum. I have never seen this complication. Will not treatment of this body accomplish as much as removal? The verumontanum is a structure that was put there for a great deal more perhaps than the appendix was put in the abdomen. What direction does the semen take and what prevents the ejaculatory ducts from becoming stenosed after the operation? In 1901 I accidentally removed the top of an enlarged verumontanum. How much of it, I do not know. It did no harm. I have, however, recently doubted the harmlessness of the procedure of removing the entire verumontanum.

Dr. Frederick R. Charlton, Indianapolis: Does Dr. Rytina think he accomplishes anything more than a curetting of the verumontanum, or does he believe that he gets the entire structure? It seems to me, as to Dr. Barney, that we are on the verge of sweeping into a specialist's fad. I cannot for the life of me believe that such enormous importance attaches to the verumontanum alone as it seems to have been given during the last year or two. I have felt that we have been neglecting, perhaps only transiently, the prostate—an admittedly important organ or gland capable of infinite damage. Once thoroughly infected, I question whether it is ever completely restored. I do not know whether anyone is really working hard on chronic infectious prostatitis, and I am much afraid that in the attention we are giving to this almost insignificant structure, we are going to grasp at a shadow and miss the substance of things in this region.

Dr. Robert H. Herbst, Chicago: I cannot reconcile myself to the belief that the verumontanum is responsible for all that is charged to it. I do agree that we frequently see pathologic changes occurring in this organ, but I am thoroughly convinced that, in most instances, these are provoked by discharges from the seminal vesicles. We know that the gonococcus is the common offender in the male urethra and also how frequently this infection spreads into the seminal vesicles. It is the constant discharge of pus from the genital tract which I think is responsible for much of the so-called verumontanum disease. Furthermore, if in these cases we give the attention to the seminal vesicles which they deserve, we will see much of the trouble in the verumontanum disappear without further treatment. I believe that the disturbing element in these cases is primarily located in the seminal vesicles.

Dr. Alexander Randall, Philadelphia: I call attention to the truly unprecedented and noteworthy work of Dr. Rytina. Thorough search of the literature, last year, enabled me to find but two cursory descriptions of this important structure, the one by Burckhardt, and the other by Delbet, in Poirier and Charpy, Traité d'Anatomie. Dr. Rytina has given a most thorough description of the histology and pathology of the colliculus. The glandular hyperplasia referred to I have seen demonstrated a number of times. Often there is a most extensive hypertrophy with marked infolding of the walls of the acini; at other times the acini are distended with secretion; a third type is that of sclerosis and extensive growth of connective tissue. I feel that one must be careful and should try all other forms of treatment before having recourse to such a radical removal as Dr. Rytina has described, but that this operation has its appointed place. That truly remarkable results can be obtained thereby in carefully selected cases, has been proved to my own satisfaction in the few cases in which I have considered removal to be indicated.

Dr. A. G. Rytina, Baltimore: The microscopic picture of the sinus pocularis somewhat resembles the structure of the normal seminal vesicles, as Dr. Barney pointed out. In the beginning I was in doubt whether to regard these invagination processes as true glands, but, as the lining consists of many layers of squamous epithelium, I came to the conclusion they were not glands, but they do have a secreting surface. Answering Dr. Kretschmer, the patient who had the infected verumontanum had also a chronic prostatitis. When is the operation indicated? I have only recently begun this work and am not prepared to answer this question with authority. We are carrying out extensive researches on operated and necropsy specimens in the human being and perhaps, later, I shall be able to answer that question. Dr. Keyes brought out an important point, namely, the dilatation treatment of the posterior urethra. In the future, perhaps, a therapeutic measure will be to massage the verumontanum through an endoscopic tube. I reported one case of seminal emissions in a patient who had a highly inflamed verumontanum. I made repeated applications without relief. Accidentally I pressed the endoscopic tube against the verumontanum and quite a gush of pus came out. I then injected the utricle several times with the result that the emissions and inflammation disappeared. He had a deep infection which, traveling up, infected the surface of the verumontanum. Probably we will learn later that a highly inflamed verumontanum indicates infection of the deeper structures, just as inflammation about the ureteric mouth causes suspicion of tuberculosis of the kidney. Dr. Hawkins said epididymitis was rare following applications to the verumontanum. I am sure that anybody who has made many applications to the verumontanum has seen more than one case of epididymitis resulting. Do I get the whole verumontanum? It is taken out as thoroughly as can possibly be hoped. The instrument acts as a curved knife and the verumontanum comes out almost intact. Just a very little piece at the base persists after the operation. With Dr. Herbst, I do not believe that the verumontanum causes all the symptoms accredited to it. I am carrying out this work to prove what effect the verumontanum has in so many of these sexual, urinary and referred disturbances. I believe we ascribe too much importance to it as a cause of so many diverse symptoms, and I hope to prove whether or not it is the true causative factor.

ANARTHRIA DUE TO SYPHILIS

REPORT OF TWO CASES

C. BURNS CRAIG, A.B., M.D.
Chief of Clinic (First Division), Neurological Institute
NEW YORK

Of all the forms of neurologic syphilis, the one giving rise to the most sudden, the most profound and startling display of symptoms is gummatous meningitis. Existing throughout the central neural axis, the gravest manifestations naturally arise from interruption of nerve paths in the cerebrum.

Coincident with the marked exudate of albumin and cells evident in the cerebrospinal fluid of such cases, there must be a similar perivascular exudate in the substance of the brain itself, producing, in certain cases, an ischemia of certain foci. Any cranial nerve may be suddenly put out of commission, and as a result the patient may exhibit some form of heterophoria, ptosis, single or double choked disk, unilateral or bilateral deafness, facial sensory or motor disturbances or respiratory difficulty.

Still more bewildering are the symptoms following the blocking of the circulation in the subcortical vessels supplying the coordinating paths. An intensely interesting phenomenon results when the coordinating paths in the lenticular zone are interrupted. This zone includes the lenticular and caudate nuclei, the internal and external capsules, the island of Reil, the motor cortex and the fibers between them.

When this area is the site of disease, the resultant symptom is designated by Marie anarthria, and is the simple motor aphasia of the older writers. There is no paralysis of the vocal organs, but the patient simply does not remember how to speak. A lesion so isolated as to produce this condition alone could hardly be expected in so general an infection as syphilis, but in the following cases this was the most remarkable symptom.

CASE REPORTS

Case 1.—*History.*—A Russian Jewess, aged 35, was brought to the Neurological Institute, March 23, 1914, because her friends thought she was "losing her mind." She apparently did not understand what was said to her, and they could not understand her when she attempted to speak. In fact, during the past week she had become wild and seemed not to know what she was doing. She attempted on one occasion to jump from the window.

She had been in this country four months and during that time she had spoken with great difficulty and complained of severe pains in her head and weakness of her right leg and arm. During the last day on board ship, four months previously, she asked for a glass of water. When it was brought it was observed that she was unable to hold the glass in her right hand and, furthermore, that any attempt at speech failed utterly. Previous to this she had made no complaint of feeling ill. This condition lasted over night and she was again able to speak the following morning. The patient was taken to her sister's house and the right-sided weakness improved slightly.

Suddenly four weeks later she again became completely unable to speak for three consecutive days, although there was no paralysis of lips or tongue. From that time until the date of admission to the hospital her speech was badly disturbed so that it was with difficulty that she made herself understood. This state gradually deteriorated so that at the time she was first seen at the hospital she was only able to utter curious guttural sounds which her sister and other native Russians said bore no resemblance to any Yiddish words.

Physical Examination.—Physical examination revealed a slender woman of 92 pounds with a dull, expressionless face. She repeatedly put her hand to her head, apparently to indicate pain. Aside from absent ankle-jerks and a slight irregularity of the right pupil there were no physical defects discovered. The pupils responded fairly well to light, possibly better to accommodation. The fundi were normal. Hearing seemed unimpaired. The face and tongue were symmetrical. There was no inequality in the tendon reflexes at the knees or in the arms, the abdominals were also equal. Gait and station were unimpaired, and there was no demonstrable difference in the strength of the extremities of the two sides. The patient's temperature was 98.4 F., pulse 80, respiration 18.

Diagnosis and Treatment.—A diagnosis of cerebral syphilis was made, which was confirmed the following day on examination of the cerebrospinal fluid.

She was then subjected to a series of intravenous injections of salvarsan with gratifying results. The record of the therapy and the effect on the serology are given in Table 1.

TABLE 1.—RESULTS OF BLOOD AND CEREBROSPINAL FLUID EXAMINATION IN CASE 1

* 360 polynuclear, 570 lymphocytes.

† 23 polynuclears, 173 lymphocytes.

‡ This and following counts were lymphocytes.

Outcome.—During the first two weeks in the hospital she kept up an incessant jargon during the day, unintelligible even to Russians, and was noisy and restless at night. She insisted on walking about and had to be restrained. During the third week the patient began to quiet down and to sleep all night. The following two weeks witnessed a complete transformation. Previously irritable and unruly, she now became calm, grateful, and ceased the harsh scolding sounds. Although she could understand no English, she understood fully her native speech and could talk fluently and rationally in Yiddish. In the course of the next month she became animated, interested in her surroundings, thoughtful in regard to others and made herself useful in every possible way. Aside from the complete restoration of speech, the change in personality was little short of marvelous.

On contemplation of what an enormous exudate 1,000 cells per cubic millimeter of cerebrospinal fluid represents, it is not surprising that grave symptoms indicative of cortical involvement are present. The altered disposition observed in the above case was probably due to exudative irritation of the cortex of the frontal lobes. The transient hemiparesis, on the other hand, was no doubt the result of a subcortical lesion in the lenticular zone, ischemic in character, due to occlusion of a small artery, caused by the pressure of the surrounding exudate.

In the following case, besides the subcortical lesion in the lenticular zone producing motor speech disturbance, we again observe cortical irritation phenomena, this time referable to the Rolandic area, as evidenced by the twitchings of the left side.

The lesion responsible for the anarthria was, doubtless, situated more superficially in the lenticular zone of Marie, as described above.

Case 2.—*History.*—A young man, 26 years of age, applied at the Neurological Institute, Oct. 6, 1913, for relief from a headache which he had had for three months. During the previous four days it had practically ceased, but had been succeeded by involuntary twitching of the left side of the mouth, left shoulder and at times the entire left side of the body. He complained further of sleeplessness and was greatly frightened two days previously by complete loss of the power of speech. He understood what was said and knew what he desired to say but was unable to utter a word. Four months ago he had had a chancre but no secondary manifestations.

Physical Examination.—Searching physical examination revealed absolutely no evidence of organic disturbance save a lower neuron paralysis of the left seventh cranial nerve. He was well developed, skin and mucous membranes were negative, and no glandular enlargement was discovered. The ocular muscles were efficient, the pupils normally active and the fundi negative. There was no pathologic reflex and the tendon and skin reflexes were active and equal. Sensation was not affected.

On the day of his arrival at the hospital the patient spoke with great effort, the difficulty being the expression of the desired words; in fact, many of his replies made no sense at all and were a mere succession of syllables or words. On the other hand, he seemed to comprehend what was said to him.

Diagnosis and Treatment.—A diagnosis of syphilitic exudative meningitis was made. Lumbar puncture corroborated this and a full dose of neosalvarsan was administered intravenously on the day of his admission. It was the intention to make a complete aphasic status on the following day, but during the succeeding twelve hours a phenomenal response to the arsenical treatment occurred. The next morning he could speak without difficulty and carried on conversation in an entirely rational manner. There was also striking improvement in the facial paralysis. There was discoverable at this time, however, impairment of both orientation and memory. He was placed on a mixed treatment of neosalvarsan and mercury as shown in Table 2 and complete recovery resulted.

TABLE 2.—RESULTS OF BLOOD AND CEREBROSPINAL FLUID EXAMINATIONS IN CASE 2 UNDER NEOSALVARSAN AND MERCURY

‡ 5 injections of salicylate, ℳ xv.

§ Weekly salicylate, ℳ xv.

It is in cases of neurologic syphilis such as these that arsenical therapy has brought about the most striking results. The symptoms in these cases were so grave and the transformation wrought was so complete that an account of them was judged worthy of record.

149 East Sixty-Seventh Street.

Evidence and the Scientific Mind.—The unscientific mind possesses but two compartments, one for truth and one for error. . . . The scientist, however, recognizes no such compartments, for absolute truth and absolute error are unknown to him. After weighing the evidence furnished, his decisions consist only in selecting the degree of his confidence that is merited by that evidence.—G. W. Stewart, *Science*.

SPRUE TREATED BY EMETIN HYDROCHLORID *

FERDINAND SCHMITTER, M.D.
Captain Medical Corps, U. S. Army
WASHINGTON, D. C.

In a report[1] to the Surgeon General of the Army dated Sept. 30, 1913, I noted six cases in which the patients were suffering from sprue, all of whom markedly improved under treatment by emetin hydrochlorid (alkaloid) given hypodermically in ½ to 1 grain doses daily for five days. Since then I have observed two more cases and four have been reported to me by other medical officers, in which like results were obtained, making a total of twelve cases in which the patient's symptoms cleared up under the same treatment. One of these patients had concurrent entamebic dysentery. No case of sprue which has failed to respond to this treatment has come to my attention.

Permanent results were not observed because most of these patients returned to the United States shortly after receiving the treatment. In only one case have I been able to follow the course long enough to note permanent results.

The patient, a man, aged 40, had an unimportant previous history which was negative for lues. Wassermann and luetin reactions were negative. He was first taken ill in September, 1906, at which time he weighed 216 pounds. During the following seven years his bowels never acted normally, digestive disturbances were never absent, and vomiting was frequent and persistent. He was almost continually under treatment both in and out of hospital, usually improving slightly under hospital regimen only to relapse soon after leaving. He took various treatments, including yellow santonin, and diets of buttermilk, raw beef, strawberries, apples and bananas. In 1908, when his mouth became inflamed and tongue raw, his disease was for the first time positively diagnosed as sprue. At this time his sexual power began to wane and was completely lost two years later, and during the three years following he never had an erection or sexual intercourse. In 1912 he went to Spain where he took the strawberry-diet treatment. Then he went to the United States where he was further treated but without improvement, and on the advice of his family physician he returned to the Philippine Islands for the purpose of closing his business affairs, arriving here in May, 1913. At that time his weight was 106 pounds. He then took a course of treatment consisting of old yellow santonin (chromosantonin) in olive oil supplemented by buttermilk diet. There followed a period of slight improvement during which he gained 16 pounds, which was succeeded by a relapse in which he lost 5 pounds.

Sept. 18, 1913, the patient came under my care and the emetin treatment was begun. At this time he weighed 117 pounds, his face showed the bronzed patches on a pale skin so common in sprue. His body was emaciated and his feet were swollen, with slight pitting on pressure. His epigastrium was protuberant and he had a tight feeling of distress extending from the middle to the costal margins. His tongue was glazed, raw and beefy, with ulcers on the dorsum, edges and at the frenum. Emetin hydrochlorid in 1-grain doses was administered hypodermically once daily for five days. The day following the first injection improvement in the ulcers was noted and they continued to improve steadily until completely healed. While receiving the treatment he complained of the activity of his bowels, but one week after the first injection he said that he felt better than he had in a long time. Four months after treatment he weighed 156 pounds. His tongue was still raw but he said that it gave him no subjective symptoms. His appetite and enjoyment of food were excellent. About this time his sexual power which had been lost for three years began to return. By the fifth month he had intercourse and by the sixth month he was normal sexually and has remained so. At the present time, the eleventh month after treatment, he is strong, presents a stout, muscular appearance, his complexion is clear, tongue clean, and there is no evidence of sprue remaining. Weight is 177 pounds. The consistent gain in weight and strength is the more remarkable because the patient under business pressure during the past ten months has been doing without luncheons and working steadily until late at night.

New and Nonofficial Remedies

The following additional articles have been accepted by the Council on Pharmacy and Chemistry of the American Medical Association. Their acceptance has been based largely on evidence supplied by the manufacturer or his agent and in part on investigation made by or under the direction of the Council. Criticisms and corrections are asked for to aid in the revision of the matter before publication in the book "New and Nonofficial Remedies."

The Council desires physicians to understand that the acceptance of an article does not necessarily mean a recommendation, but that, so far as known, it complies with the rules adopted by the Council.

W. A. Puckner, Secretary.

CANTHARIDIN. — Cantharidinum. — $C_{10}H_{12}O_4$, the anhydride (lactone) of cantharidic acid.

Actions and Uses.—Preparations of cantharidin are used in place of corresponding preparations of cantharides and have the advantage of being cleanly and more uniform in strength. Cantharidin is recognized by the British, French and Swiss Pharmacopeias.

Dosage.—From 0.00025 to 0.0005 Gm. (1/240 to 1/120 grain).

Cantharidin may be obtained from various species of *Cantharis* or of *Mylabris*. It may be prepared by digesting powdered cantharides with a mixture of concentrated sulphuric acid and acetic ether at ordinary temperature, then mixing with barium carbonate and exhausting the mixture with acetic ether. The solvent may be removed by distillation and the residue allowed then to stand for some time to allow the cantharidin to crystallize. The resulting crystals may be washed with petroleum benzin to remove the fat and then recrystallized from hot alcohol.

Cantharidin occurs as colorless glistening, inodorous crystals; 0.1 Gm. on incineration should leave no weighable residue. Cantharidin is very slightly soluble in water, petroleum benzin or alcohol (90 per cent.); more soluble in chloroform (1:65), in acetic ether (1:150), and in acetone (1:40), and is soluble also in fixed oils. A 0.1 per cent. solution in a fixed oil raises blisters when kept in contact with the skin. The melting point is from 210 to 212 C. Cantharidin slowly volatilizes at 100 C., more rapidly at higher temperatures. It is soluble in solution of sodium hydroxide, the solution depositing crystals of Cantharidin when acidified. Gently warmed with sulphuric acid it yields a colorless solution, from which it is separated unchanged when freely diluted with water.

BENZENE, MEDICINAL. — Benzenum Medicinale. — Medicinal Benzol.—Crystallizable Benzol.—C_6H_6.—A liquid consisting almost entirely of benzene (cyclohexatriene).

Actions and Uses.—When swallowed, this drug usually produces a sensation of burning in the stomach. Benzene is a narcotic which, when swallowed or inhaled, produces vertigo, delirium and tonic convulsions followed by deep sleep; 30 c.c. (1 ounce) of nearly pure benzene has proved fatal. In some cases of chronic poisoning petechial spots, due to small hemorrhages, have been observed. These spots have been attributed to fatty degeneration of the blood-vessels. It produces leukocytosis followed by leukopenia with an occasional increased number of erythrocytes. Larger doses may produce an aplastic anemia. It has been stated that the aplastic anemia is due to a contamination of the drug with nitrobenzene or aniline. Benzene has been used occasionally on account of its narcotic properties and has also been used as an intestinal antiseptic. It is, however, rarely used for these purposes at the present time. It has been somewhat extensively used in the treatment of leukemia. Moderate doses cause a rapid destruction of the leukocytes, especially the lymphocytes. This action is accompanied by an improvement in the subjective symptoms and, in some cases, by a marked reduction in the size of the spleen. In many cases the lymphocytes have been reduced to the normal figure. In others the number of leukocytes has still remained high, although the size of the spleen was reduced. In many cases the improvement is such that an apparent cure is produced. However, a large number, if not all, of these patients relapse or succumb to the toxic action of the benzene. It is recommended to stop the administration of this drug before the leukocytes are reduced to the normal level. Benzene has also been used in a few cases of Hodgkin's disease and in cases of polycythemia. The effect of benzene on the leukocytes is largely enhanced by the previous or simultaneous treatment with the Roentgen ray. The value of benzene in leukemia is not established and caution against too large and too long continued dosage should govern its employment.

Dosage.—0.5 to 1 Cc. (8 to 15 minims) given four times a day. Medicinal benzene may be given in capsules or in an emulsion or may be administered by rectum. Frequent examinations of the blood should be made during the administration of medicinal benzene to determine when it is advisable to suspend the administration of the medicine.

Non-Proprietary Preparation.

Benzene, Merck, H. P., Crystallizable.—Merck & Co., New York.

Medicinal benzene is prepared by fractional distillation of the light oil of coal tar and is a colorless, mobile liquid, posessing a strong characteristic but not disagreeable odor and a burning taste. It has a specific gravity of from 0.881 to 0.885 at 15 C.

Medicinal benzene is insoluble in water but soluble in 90 per cent. alcohol and in carbon disulphide; it is miscible with absolute alcohol and ether. Medicinal benzene is a solvent for bromine, iodine, sulphur, phosphorus, fatty and volatile oils, rubber, gutta-percha, wax, various resins, a large number of alkaloids and some aromatic acids.

Medicinal benzene boils at from 79 to 82 C. It is inflammable and burns with a luminous and sooty flame. When cooled to 0 C., medicinal benzene solidifies. If cooled slowly it crystallizes in rhombohedral prisms, which melt at about 6 C.

It is neutral toward litmus.

Medicinal benzene is not affected by cold sulphuric acid but is soluble in fuming nitric acid, without liberating nitrous vapors. When poured into water the mixture separates and deposits oily globules of nitrobenzene, which can be identified by its characteristic bitter almond odor.

If 2 Cc. of medicinal benzene be shaken with 0.5 Cc. concentrated sulphuric acid and 1 drop of fuming nitric acid, no green or blue tint should be produced.

LEUKOCYTE EXTRACT.—An extract of the leukocytes obtained from exudates produced in the pleural cavities of rabbits or other animals by the injection of an irritant.

Actions and Uses.—Leukocyte extract is believed to increase the immunizing power of the organism into which it is injected.

It is said to be useful as an aid to the action of specific serums or antitoxins and vaccines.

It is claimed to be useful by itself in cases in which the correct bacteriologic diagnosis of the infection cannot be obtained. Its use is still in the experimental stage.

Dosage.—The extract is injected subcutaneously under strict aseptic precautions. The dose may be repeated daily or less often as indicated by the response after injection.

Leukocyte extract is prepared by inciting a purulent exudate in the pleural cavities of rabbits or other animals through the injection of sterile vegetable protein solution.

After the exudate is collected in sufficient quantities, it is aspirated under strict aseptic precautions from the pleural cavities. It is centrifuged and extracts are made of the leukocyte sediment after determining that the exudate is free from bacteria.

LEUCOCYTE EXTRACT-Squibb.—A leukocyte extract prepared according to the method of Hiss.

Dosage.—Not less than 10 Cc. Leucocyte Extract-Squibb is furnished in syringes containing 10 Cc.

Manufactured by E. R. Squibb and Sons, New York City.

It is claimed that biologic and clinical tests have proved leukocyte extract, Squibb, to be of high potency and efficiency.

NON-PROPRIETARY BRANDS OF ACCEPTED ARTICLES

Silver Citrate, Merck.—On heating it yields not less than 62 per cent. of metallic silver. Merck and Co. New York.

Silver Lactate, Merck.—On heating it yields from 50 to 51.5 per cent. of metallic silver. Merck and Co., New York.

Digitoxin, Merck.—Merck and Co., New York.

Therapeutics

PREVENTION IS GREATER THAN CURE

(Continued from Vol. LXIII, page 2291)

XIV

THE COMMON INFECTIOUS DISEASES

Before taking up these diseases separately, it may be well to quote Vaughan's Harvey Lecture[1] as to what is scientifically understood by a germ pathogenic to man, and just what infection means. Briefly, Vaughan says that it is the protein poison produced by the germ that causes symptoms. If the germ does not find in our bodies an albumin suitable for its food, it dies and is not pathogenic to us. Also, if our tissues, in individual cases, can produce antibodies or opposing serums or antitoxins rapidly enough to overcome a germ which does find suitable food albumins in us, it will die before it intoxicates us, and we become, at this time at least, immune. Vaughan also says that acute disease or intoxication results when there is rapid multiplication of the infecting germs that find suitable pabulum, its protein toxins causing rapid sensitization of our systems, and a resulting fever which is of benefit. If the production of these pathogenic germs is slow, the result is a chronic infection, and when the proper albumin for the food of these germs is formed only in restricted areas, the result is a local infection.

COLDS

Next to disturbances of nutrition in infants and young children, colds, inflammations of the air passages, are the greatest menace to health. Colds far surpass in frequency any other disease condition. Generally, the older the child, the less frequent the colds, but the susceptibility to catching cold, or the cold habit is of very frequent occurrence in individual children, in some youths, and even in adults. There is no immunity acquired by surviving a coryza, a pharyngitis or a bronchitis; in fact, ordinarily, the person is at least temporarily more susceptible to taking or developing a fresh cold. This may not be quite true of an influenza or grip cold, because many persons have a real or pseudogrip attack early in the fall or winter and are then more or less immune from acute attacks during the rest of that season; but there seems to be no doubt that the influenza bacillus leaves a patient temporarily, at least, more susceptible to other more dangerous germs, as the pneumococcus or tubercle bacillus. Consequently, besides the immediate debility that an acute cold causes, the possibility of opening the way for the entrance of more serious disease should cause every cold to be considered seriously and treated energetically. Also, it should be the object of every mother, nurse, family physician, schoolteacher, medical inspector, board of education and board of health to inaugurate every means possible to prevent colds, that is, to develop the resisting power of the individual; to see that the child is properly clothed; to see that the house and schoolroom air is as free as possible from dust and germs, and that it contains the proper amount of moisture, and to take measures to prevent individual contagion and widespread irritation of the upper air passages from irritants in the air of buildings and localities.

While it is asserted by some that acute colds are always due to germs of some kind, it is conceivable that a too dry atmosphere, which is the condition in so many houses to-day, may so irritate or congest the nostrils as to allow the least irritant to cause at first a simple inflammation of the mucous membrane, which congested area may later pick up and harbor, or cease to kill, germs. It seems to be an established fact that good outdoor air does not predispose to colds as much as indoor air, and it is a fact that persons whose occupation is indoors are more liable to have colds than those whose occupation is outdoors. Whether or not every cold is due to a contagium or to a germ, chilling, whether indoors or outdoors, certainly predisposes to colds. It is quite probable that chilling of the surface of the body congests the inner organs and possibly the mucous membranes of the air passages. If the mucous membrane of the nose is congested, it more readily becomes inflamed by irritation or by germs.

---

[1] Vaughan, Victor C.: The Phenomena of Infection, The Journal A. M. A., Feb. 21, 1914, p. 583.

To repeat, every cold, especially in a young child, should be considered serious. The possibility and the frequent occurrence of complications such as middle-ear inflammation, inflammation in one of the accessory sinuses of the nose, broncho-pneumonia or lobar pneumonia must always be a subject for consideration and prevention if possible. Colds and throat infections are also likely to cause enlarged cervical glands and perhaps enlarged bronchial glands. Any one or more of these glands may become infected with tuberculosis. Again, most colds, if not all, are contagious, and are transmitted by contact through families or close associates, and are especially spread by contact in schools.

The first step in the prevention of colds is to ascertain if the child properly breathes through its nostrils. Adenoids and greatly enlarged tonsils should be operatively treated. Hypertrophied mucous membrane or deformed nostrils should be surgically treated, if deemed advisable. The nutrition of the child must be good; if a child is underfed, he must receive more food. If a child is anemic, he must be properly treated with fresh air, good food and iron. Any chronic disease must be discovered. Swabs should be taken from the nose and throat, and cultures made to ascertain if the child is harboring a recognizable pathogenic germ.

ACUTE CORYZA

This acute nasal catarrh, often called a "cold in the head," is of frequent occurrence in some regions, especially near the seacoast, and occurs repeatedly in certain persons who seem to have a susceptibility to inflammation in the nose. Some persons cannot be exposed to a single draft on any part of the body without an acute coryza starting. Whether their mucous membranes are in such a condition as to allow a recurrence of inflammation from dust irritants or from the congestion caused by chilling, or whether they more or less constantly harbor germs which cause another acute infection, if the mucous membrane is again congested, is a question that has not yet been positively determined. It is supposable, however, that while most acute nasal catarrhs are due to infectious germs, more or less chronically hypertrophied mucous membrane and more or less sluggish circulation in this membrane may allow simple non-infectious catarrhs to occur when irritation of any kind is applied. Other persons who do not have this susceptibility may become chilled, may be subjected to violent cold, damp winds, and may even get wet and still never develop a nasal catarrh. Just as large tonsils more readily catch germs and become diseased, or more readily harbor germs and have recurrent inflammations, so hypertrophied mucous membrane of the nostrils becomes susceptible to reinfection or to reirritation. Frequent acute colds, more or less constant subacute inflammations, or chronic catarrh may result from such a condition.

Some persons are susceptible to certain kinds of irritants, whether it be a particular kind of dust, a particular kind of pollen from plants, or the emanations or odors from stables, horses, etc. If this susceptibility is in excess, or occurs at certain times of the year, the patient becomes a so-called hay-fever or rose-fever sufferer, and then shows symptoms of anaphylaxis.

The pathology of any acute mucous membrane inflammation is divisible into stages, the first being that of congestion and dryness of the surface. With this congestion there is swelling due to dilatation of the blood-vessels and more or less erection of the tissue, and with this swelling, if the mucous membrane is in a narrow canal, there is more or less obstruction, with discomfort, or even pain.

The next stage of the mucous membrane inflammation is the outpouring of a more than normal amount of mucus. The surface of the membrane then becomes moist, and the pain or discomfort becomes less as the tissues become less congested, owing to more or less extravasation of watery secretion and white blood-corpuscles which sooner or later may become pus. This extra secretion is propelled by gravity or by cilia or by voluntary expulsive methods to some external orifice, and the patulency of the part gradually returns. If this inflammation persists the secretion becomes more and more purulent. With a good outlet, and where the irritating and purulent secretions are not too long retained, the tendency of the mucous membrane is to recover, the pus gradually disappears, the secretion becomes mucopurulent, then mucus but in an abnormal amount, and finally the mucous membrane becomes normal, with its normal amount of mucous secretion. However, for some time this membrane is more susceptible to recurrences of inflammation.

The mucous membrane of the nose and throat in some persons may become abnormally dry. This condition is more difficult to treat, and even prolonged treatment may not cause it to become normal. Such persons have what is termed dry catarrh, and unless great care is taken, retain dry strings or plaques of secretion that putrefy and cause a disgusting odor to the breath, a condition termed ozena.

With a localized acute inflammation of the mucous membrane there may or may not be fever, depending on the susceptibility of the individual to an irritation, some persons developing fever readily, others having no fever except under serious provocation.

Applying this pathology to an acute coryza, it is readily understood, with a damming up of the passages from congestion and secretion, that germs, both by their own movements and by pressure, may migrate or be forced into some of the sinuses surrounding the nostrils, and the frontal sinuses are those that most frequently suffer. This is the cause of the frontal headache from the congestion which occurs with most colds, and of an actual frontal sinusitis when infection actually enters these regions. If the same inflammation occurs in the nasopharynx, the mouths of the eustachian tubes may become blocked, and middle ear congestion from aspiration of the air is caused. Also the germs of infection may migrate up these tubes and middle ear inflammation develop.

SATURDAY, JANUARY 2, 1915

DEATHS OF PHYSICIANS IN 1914

During 1914 the deaths of 2,205 physicians in the United States and Canada were noted in The Journal. Reckoning on a conservative estimate of 153,000 physicians, this is equivalent to an annual death-rate of 14.41 per thousand. For the twelve previous years the death-rates were as follows: 1913, 14.64; 1912, 14.13; 1911, 15.32; 1910, 16.96; 1909, 16.26; 1908, 17.39; 1907, 16.01; 1906, 17.2; 1905, 16.36; 1904, 17.14; 1903, 13.73, and 1902, 14.74. The average annual mortality for the period from 1902 to 1914 inclusive was therefore 15.71 per thousand. The chief death causes in the order named were: senility, heart disease, cerebral hemorrhage, pneumonia, accident and nephritis. The age at death varied from 23 to 99, with an average of 60 years, 11 months and 6 days. The general average of age at death since 1904 is 59 years, 9 months and 19 days. The number of years of practice varied from 1 to 75, the average being 33 years, 9 months and 29 days. The average for the past eleven years is 31 years, 11 months and 22 days.

Causes of Death.—There were 225 deaths assigned to general diseases; 229 to diseases of the nervous system; 296 to diseases of the circulatory system; 145 to diseases of the respiratory system; 93 to diseases of the digestive system; 125 to diseases of the genito-urinary system; 3 to diseases of the skin; 3 to diseases of the bones; 411 to senility; 27 to suicide; 111 to accident; 13 to homicide, and 79 after surgical operations. Among the principal assigned causes of death are senility, 411; heart disease, 211; cerebral hemorrhage, 185; pneumonia, 124; accident, 111; nephritis, 108; malignant disease, 56; tuberculosis, 48; appendicitis, 36; diabetes, 33; suicide, 27; septicemia and arteriosclerosis, each 25; angina pectoris, 23; typhoid, 17; gastritis, 14; myocarditis and homicide, each 13; cirrhosis of liver, 11; pernicious anemia, 10; endocarditis, 9; meningitis, 8; rheumatism and cholecystitis, each 7; bronchitis, 6; influenza, locomotor ataxia and scarlet fever, each 5; erysipelas, tetanus, pellagra, general paralysis of the insane, aneurysm, intestinal obstruction, peritonitis, Hodgkin's disease and mastoiditis, each 3; dysentery, syphilis, drug addiction, mental alienation, pleurisy and carbuncle, each 2 deaths, and malaria, small-pox, plumbism, chorea, embolism, ulcer of stomach, ulcer of duodenum, hernia, Addison's disease and retropharyngeal abscess, each 1 death.

The causes assigned for the 111 deaths from accident were: automobile, 25; falls, 17; poison, 10; automobile and railway, 9; railway and drowning, each 8 (of the latter, three were drowned in attempting to save lives); street car, 6; fracture of hip, 5; asphyxiation, firearms and sunstroke, each 4; burns, by animals, freezing and lightning, each 2, and explosion, runover and runaway, each 1. The 27 physicians who ended their lives by suicide selected the following methods; firearms, 13; poison, 10 and asphyxiation, strangulation, cutting instruments and cause not stated, each 1. Of the 13 homicides, 10 were due to firearms, 2 to clubbing or beating and 1 to stabbing. Of these, 4 occurred in feuds or affrays.

Ages.—Of the decedents, 61 were between the ages of 23 and 30; 199 between 31 and 40; 319 between 41 and 50; 432 between 51 and 60; 477 between 61 and 70; 404 between 71 and 80; 193 between 81 and 90; while 21 were more than 90 years of age. The greatest mortality occurred at the age of 62, when 68 deaths were recorded, at 70 with 61 deaths; at 59 with 59 deaths; at 54 and 55 with 58 deaths each; at 74 with 54 deaths, and at 69 when 51 died. There were 7 deaths each at 91 and 92; 3 at 95; 2 at 93, and 1 death each at 94 and 99.

Years of Practice.—By periods of ten years, the physicians died as follows: in the first decade, 162, of whom 7 had been in practice less than one year and 12 less than two years; in the second decade, 304; third decade, 421: fourth decade, 553; fifth decade, 443; sixth decade, 225; seventh decade, 84, and eighth decade, 5, three of whom had been in practice 70 years and one each 71 and 74 years.

Military Service.—During the year, 275 died who had served in the Civil War, and of these 90 had followed the Lost Cause; 83 were medical officers of United States Volunteers, 2 were medical cadets, 10 served in the hospital corps and 2 had been army nurses. There were 2 veterans of the Mexican War; 2 had served in campaigns against the Indians; 17 had been in the Spanish-American War and 7 had been medical officers in foreign wars. The Army lost 9 officers, one of whom was surgeon-general, 3 members of the Medical Reserve Corps and 8 contract or acting assistant surgeons. The Navy lost 12 medical officers, the Public Health Service 10 officers, and the Organized Militia 28 medical officers, of whom 9 had attained the grade of surgeon general.

Medical Positions.—Medical colleges sustained the loss of 146 professors, lecturers, instructors and demonstrators; hospitals lost 290 members of staffs; municipalities, townships and counties, 165 health officers, and school boards or boards of education, 57 members. There were 29 deaths of members of state boards of health, medical examination and registration and charities; 29 of coroners and medical examiners and 84 of railway surgeons.

Civil Positions.—Of those who died, 1 had been a member of Congress; 1 an ambassador; 7 members of state senates; 39 members of the house of representatives; 39 had been mayors; 25 aldermen; 39 had served in various civil positions; 14 had been postmasters; 20 editors of medical or lay journals; 11 had been clergymen, of whom 2 were foreign missionaries, and 6 had been attorneys.

THE FOURTH CENTENARY OF VESALIUS

Amid these stirring times when the invasion of Belgium and the news of the destruction of Louvain—an ancient seat of learning—have been proclaimed far and wide, we recall the name of an illustrious Belgian man of science whose work has marked an epoch in the history of medicine. The week just closing celebrates the four hundredth anniversary of the birth of Andreas Vesalius, the father of modern anatomy. Born in Brussels on the last day of the year 1514 of an ancestry of physicians and learned men, from whom he inherited a leaning toward scientific pursuits, Vesalius studied at the University of Louvain, later at Paris, again at Louvain and in Italy. He died in 1564.

To appreciate the service which Vesalius rendered to the cause of science, it is necessary to remember that medicine in the sixteenth century was still under the dominance of the doctrines of Galen. When one recalls the almost undisputed sway of Galen's influence for more than a thousand years it is easier to understand how difficult must have been the path of the reformer and how seemingly hopeless the attempt to overthrow the blind adherence to authority. The great importance of Vesalius lies in the fact that he succeeded, where others had failed, in inaugurating a new era of observation and reason. He dared to dispute the words of his masters and to demonstrate directly on the cadaver the error of numerous anatomic claims of medieval medicine. If the anatomist of antiquity stated that the lower jaw-bone of man is divided, as it is in many mammals, Vesalius was ready to prove by dissection that in the human body it is actually a single bone. He could show on the human subject that the sternum has three parts instead of the alleged eight. He found no need of defending the dictum that the thigh-bones were curved in accordance with Galen's teaching. As for the accepted dogma that man should have one less rib on one side, because of familiar scriptural accounts, Vesalius preferred to dispute the contention of the theologians.

The careful study of descriptive anatomy by Vesalius and his successors, in the words of Sir William Osler, restored to men the lost art of clear, independent vision. The slavish obedience to authority which characterized the thought, and more particularly the methods, of the Dark Ages, received a setback. From the point of view of the literature of the medical sciences, special mention should be made of the publication of the book by Vesalius which laid the foundation of modern biologic sciences. This great classic on the structure of the human body, entitled "De Humani Corporis Fabrica," appeared in Basel in 1543, and marks the beginning of modern anatomy. Evidently sound knowledge of structure was necessary before any permanently tenable conclusions respecting the functions of the body could be drawn. In this respect the descriptive text of Vesalius was the forerunner of the subsequent developments in physiology inaugurated by William Harvey.

No reference to the masterpiece of Vesalius would be complete without a tribute to the splendid drawings and highly artistic plates with which the work was illustrated. Just at the present time when some emphasis is again being placed on the quality of the illustrations with which modern texts are being supplemented, it is interesting to note that for executing his plates Vesalius secured the services of a Belgian artist, John Stephen de Calcar, said to be a gifted pupil of Titian.

In estimating the claim of Vesalius to renown, it has well been said that what he did was not so much to discover great truths as it was to overthrow dependence on authority and reestablish the scientific method of ascertaining truth. "The spirit of progress," Locy writes, "was now released from bondage." And with his characteristic felicity of exposition Sir Michael Foster adds: "He taught in such a way that his disciples, even when they thought him greater than Galen, never made a second Galen of him; they recognized that they were merely following his teaching as a whole when they appealed to observation to show that in this or that particular his teaching was wrong. After him, backsliding became impossible; from the date of the issue of his work onward, anatomy pursued an unbroken, straightforward course, being made successively fuller and truer by the labours of those who came after."

Last April a conference was called under the auspices of the Société des Amis de l'Université de Paris, at the Sorbonne, to consider the subject of the fourth centenary of the great anatomist.[1] Vesalius died on one of the Ionian Islands, where he was landed during a return trip from a pilgrimage to Jerusalem after he had been compelled, it is said, to make a pilgrimage to the Holy Land to clear his soul of sacrilege because of a post-mortem examination made by him. It was intended to erect a monument last August under the auspices of the Belgian government, on the island of Zante where Vesalius died. We hope that when the present hostilities are over some fitting tribute may still be made possible to commemorate the man who placed the structure of the human body in a new light.

---

STOMACH BITTERS

The prescription of "bitters" of various sorts belongs to those inherited procedures in practical medicine that antedate the modern period of scientific criticism and therapeutic skepticism. Why they are ordered, or what they really accomplish for the person who takes them, has usually either been answered in only the vaguest terms, or overlooked entirely by teachers of therapeutics. As a rule, these "bitters" are believed to stimulate the appetite. Bitters have even been grouped into classes, such as "pure bitters," of which calumba is an example; astringent bitters, to which the decoction of cinchona belongs, and aromatic bitters, including cascarilla or orange. Persons who eat too much and exercise too little were at one time wont to take "sherry and bitters" before dinner "to stimulate the appetite."

So far as the reputed action of bitters is subjective, producing an impression due to suggestion on the individual rather than to any real pharmacologic action of the drugs involved, it is not easy to test the hypothesis of their efficiency in a convincing experimental way. Carlson[1] and his collaborators at the University of Chicago have lately pointed out that the generally accepted assumption of an increased appetite and hunger produced by bitters might result in a variety of ways. The stomachics may directly inaugurate or augment hunger contractions of the empty stomach, or hasten the reappearance of gastric hunger contractions by facilitating secretion and peristalsis, and final emptying of the stomach. They may augment the appetite directly by stimulation of gustatory and other sensory nerves of the mouth, esophagus, or stomach. Finally, the bitters might even be conceived to facilitate the impulses from the mouth so as to bring feeble hunger and appetite sensations more prominently into consciousness.

Appetite and hunger are by no means identical sensations. The relation of bitters to the sensation of hunger is amenable to experimental investigation in view of the now established facts in relation to the genesis of the latter.[2] The hunger sensation is evidently produced by certain types of contraction of the empty stomach. These can be recorded accurately. Hunger pangs are absent so long as the empty stomach is relatively atonic and quiescent.

The Chicago investigators[1] have now studied the effect of such bitters as the tinctures of gentian, quassia, calumba, humulus, condurango, and the elixir of quinin, strychnin, and iron on the hunger sensation in man and animals. The influence of the bitters in the mouth and in the stomach was tested separately. When they are introduced, in therapeutic quantities, directly into the stomach so as not to come into contact with the mouth or esophagus, these drugs have no direct action whatever on the hunger mechanism. When quantities sufficiently large to produce a demonstrable effect are introduced in this fashion, the action is always in the direction of inhibition. Introduced into the mouth, the action of stomachics and bitters is like that of all sapid substances. They stimulate the taste organs and nerves of general sensation in the mouth, and cause reflex inhibition of the gastric hunger contractions. It will thus be seen that the bitters have no effect whatever in the way of augmenting hunger contractions and the attendant sensations.

It is conceivable that aside from the possibilities already described, the "bitter tonics" are capable of exerting a favorable action on the secretion of the gastric juice, and thereby promoting the progress of digestion in the stomach. This question likewise has been put to the direct test of experiment by Carlson and his collaborators. From the facts reported in this issue of The Journal,[3] the bitters have shown nothing to commend them from the standpoint of increasing digestive efficiency. Whether introduced into the mouth or directly into the stomach, they produced no changes in the acidity or in the pepsin concentration of gastric juice collected either in man or in animals.

This does not exhaust all the possibilities of explanation for the alleged value of these stomachics, especially in digestive disorders. Nevertheless it seems settled that neither the hunger sensation nor the gastric secretory mechanism is affected in the way that many have been led to suppose. The experiments of Carlson were done on normal individuals, whereas bitters are usually prescribed in anorexia arising in relation to alimentary disorders. To postulate some different response in the pathologic as contrasted with the normal individual is a favorite attitude in support of inexplicable therapeutic claims. The possibility must, of course, be admitted; but if direct tests are made on suitable subjects of disordered digestion, we venture to predict, with Carlson and his co-workers, that the results will be the same as those reported on normal men.

---

[3] Carlson, A. J.: Contributions to the *Physiology* of the Stomach, XXI, The Supposed Action of the Bitter Tonics on the *Secretion of* Gastric Juice in Man and Dog, The Journal A. M. A., this issue, p. 15.

These new investigations on the possible functions of stomachics and tonic bitters serve to dispel another of the long-established beliefs in the potency of certain popular remedies. As Carlson has well said, even if the therapeutic doses of such tonics are harmless, their use contributes to the drug habit which emphasizes the desire to "take something" instead of "do something." The patient may perhaps be deluded into the belief of "being done good," and may exhibit the benefit of psychologic medicine. After all, the really efficient agencies for improvement in alimentary and nutritive disorders are in most instances not to be found in suggestion or stimulation, but in a well-ordered regimen of work, rest, and diet.

VIEWS REGARDING PNEUMONIC PLAGUE

The outbreak of the great pneumonic plague in Manchuria a few winters ago afforded the first larger opportunity to study the pathologic anatomy of this disease and to examine histologically the lesions that are produced by it. To the earlier reports and particularly to those of the American investigators, Strong, Crowell and Teague,[1] are now added the notes collected by Dr. Wu Lien-Teh, director and chief medical officer of the North Manchurian Plague Prevention Service, and Prof. G. Sims Woodhead of the University of Cambridge, England.[2] They believe that the specimens examined by them afford evidence of the presence of an extremely acute septicemic condition in pneumonic plague. The heart is evidently affected by very active toxins. The liver shows typical examples of lesions produced by specific infective micro-organisms that give rise to toxic substances. The epithelium of the kidneys is modified by a similar toxic activity. It is stated that in the lungs the lesions are far less marked than one would expect were pneumonia the main or most important factor in the disease. The descriptions in the literature of the subject indicate that in plague at least two types of pneumonia, and perhaps even further modifications of these types, are to be dealt with. They differ materially from that set up by the *Diplococcus pneumoniae*, which was never found in the tissue sections.

The views of these latest investigators on the mode of infection is of more general interest. They conclude that in the Manchurian outbreak the amount of the infective material, that is, the dose of the plague bacillus, gaining access to the upper respiratory passages — to the tonsils, fauces, etc.— is of prime importance in determining the character of the septicemia or bacteriemia resulting from a pulmonary infection. It is suggested that in warm countries where the people live in the open and where the facilities and channels by which infection is communicated appear to be those provided by rats and fleas, and where the plague material is carried more directly from one patient to another, or from the rat, by the flea, to the human subject, the local reaction of the tissues and the bubo may prevent the extension of the bacteria, especially if the dose is small and the septicemic condition occurs at a comparatively late stage. If there is a good reaction of resisting tissues the disease may never become septicemic. If, however, the septicemia once develops, it is evident that the internal organs are affected much as in the pneumonic form of plague.

Applying their contentions directly to the Manchurian epidemic, which was at its height in the winter, Lien-Teh and Woodhead[2] argue that the facilities for the inhalation or ingestion of large numbers of plague bacilli were far greater than they can possibly be in warm countries where people live in the open. The patients, residing in badly ventilated houses closed because of the intense cold and artificially heated, may be regarded as living in highly infected incubators of the most approved kind. Septicemias are rapidly developed; and although the lung may in a certain proportion of cases be the primary seat of infection, the late lung symptoms observed seem to point to the occurrence of a secondary pneumonia in a certain proportion of the cases examined clinically.

We have already referred to Teague's views regarding the spread of pneumonic plague.[3] The essence of the contentions put forth in the contribution from the Cambridge pathologic laboratory consists in ascribing the fatal severity of the Manchurian epidemic to the fact that the dose of infective material was always massive and entered by always open and slightly resistant portals. Under such conditions the prognosis is bad. When the advance of the *Bacillus pestis* is so interfered with that not only a local, but a general immunity may be acquired before the bacilli can reach the blood in any considerable numbers, the virulence is greatly lessened.

WATER AS A GASTRIC STIMULANT

It is considered by many that water should be taken sparingly, if at all, during meal time. The recommendation to avoid the ingestion of an abundance of water along with the food is not without an underlying belief in its therapeutic propriety and helpfulness. A custom so well established must express some supposed efficiency of action. The basis for the widely circulated rule that water should never be drunk until long after a meal is eaten probably includes one or more of the following assumptions: 1. Drinking water while eating unduly dilutes or moistens the food, thereby obvi-

ating a desirable degree of mastication and insalivation. 2. The water dilutes the gastric and other juices to an abnormal and undesirable extent. 3. The food materials are caused, by the large volume of water, to leave the stomach at an unduly early period in the gastric cycle, before the digestive changes that ought to be brought about in this organ have been satisfactorily inaugurated.

If in truth these phenomena were in whole or in part undoubtedly provoked by the ingestion of water with meals, alimentary disturbances might well be expected to follow. As a matter of fact, a large number of experimental data collected on both man and animals by Hawk and his collaborators have failed to disclose any impairment in the utilization of the foodstuffs under the influence of even exceptionally abundant intake of water at meals. This has been verified further by newer experiments of Orr[1] in Aberdeen. Indeed, Hawk goes so far as to suggest that the drinking of water with meals exerts even a desirable influence on a number of the most important of the activities and functions of the gastro-intestinal tract.[2]

Without considering in detail the various alleged beneficial effects, such as the decrease in the development of intestinal bacteria and the consequent diminution in the activity of the putrefactive micro-organisms, which are held to follow the liberal use of water with meals, we may appropriately consider one important phase of the question on which the features just cited are made to depend. Hawk has freely stated that the entrance of water into the stomach stimulates the flow of gastric juice. Not only this, but the juice as secreted has a higher concentration of acid than that produced previous to the entrance of the water. After stimulating the gastric secretion, the main bulk of the water very quickly enters the intestine, but it does not carry with it any appreciable part of the solids present in the stomach.

The assertion that water can function as a stimulant of gastric secretion is by no means a new one. The favorable action has repeatedly been demonstrated on animals, and only very recently by the Chicago physiologists Carlson, Orr and Brinkman.[3] In addition to such evidence, and to the indirect indication that water acts as a gastric stimulant in the human organism,[4] there is now offered direct proof obtained on man.[5] Bergeim, Rehfuss and Hawk note that water (ordinary or distilled), either cold (10.5 C., 50.9 F.) or warm (50 C., 122 F.), is a very strong gastric stimulant and in certain instances yields an acidity of over 100 (c.c. tenth-normal sodium hydroxid to neutralize 100 c.c of juice), in less than twenty minutes. As small a volume of water as 50 c.c. has been demonstrated to have a pronounced and immediate stimulatory power in the human stomach. In the average normal individual, water produces fully as great a stimulation (as measured by acidity and enzyme values) as does an Ewald test meal, and the acidity values follow a similar type of curve. A simple water meal might therefore be substituted in many instances for the Ewald meal, and has the additional advantage of demonstrating any food residues. It was impossible to demonstrate any pronounced glandular fatigue in the human stomach. Identical volumes of water introduced into the stomach of the same man at different times during the same afternoon yielded very similar acidity values. Under all conditions the increased acidity following water stimulation is accompanied by increased peptic activity, although the two types of values do not necessarily run parallel.

In one human subject the Philadelphia investigators obtained definite evidence that 500 c.c. of water left the stomach in from ten to twenty minutes after its introduction. The occasional efficiency of the stimulus is shown by the fact that at least 225 c.c. of gastric juice of relatively high acidity were secreted after an initial stimulus afforded by 50 c.c. of distilled water.

The stimulatory power of the water was not influenced in any uniform way by the volume of fluid introduced into the stomach. In some instances a small volume of water gave a pronounced stimulation, whereas in other tests the response was relatively less pronounced when a larger volume of water was employed. How radical the suggestions following from these newer gastric studies are is indicated by the proposal that since water stimulates the gastric glands to activity when no food is present in the stomach as well as when there is a digestive task to complete, it would seem a waste of "glandular energy" to drink water between meals. It would seem that water could best further the digestive plan when taken with meals.

A further outcome of the use of water as a gastric stimulant is the indication that the values (from 40 to 60) commonly accepted by clinicians as normal values for gastric acidity are undoubtedly too low. The acidity of the gastric juice secreted after water stimulation ranged from 50 to 120 (from 0.18 to 0.44 per cent. hydrochloric acid) with an average value of 77 (0.28 per cent. hydrochloric acid).

And It Is Still True.—". . . nothing can be more pernicious to the Health of the People, than a numerous Trade, which, to maintain itself, shall be urging the Vent of Physic in great Quantities to all Ages, Constitutions and Diseases."—R. Pitt, M.D., in The Crafts and Frauds of Physic Exposed, London, 1703.

Current Comment

THE NEW YORK TRIBUNE'S CAMPAIGN

These be parlous times for the medical faker. The New York *Tribune* recently entered the lists against the quack and the fraudulent "patent medicine" with an educational campaign that promises to have far-reaching effects. The motto of the *Tribune* is: "First to Last the Truth: News, Editorials, Advertisements." Naturally, living up to such a motto bars practically all medical advertising. But the *Tribune* has gone further. A few weeks ago it announced that it would guarantee its readers against loss or dissatisfaction through the purchase of any wares advertised in its columns. Such a step on the part of a daily newspaper is, we believe, unique. A few high-class magazines give their readers this protection, but, so far as we know, no newspaper has ever assumed such a task as that undertaken by the New York paper. As the *Tribune* says:

> Out of our armory of defences goes the comfortable old doctrine of *caveat emptor,* that favorite refuge of the newspaper whose hands are full of not over-clean advertising revenue. *Caveat emptor* is the strict letter of the law, but we shall never retreat behind it. In practice it means that the reader takes care while the newspaper takes the money. Under our system he does not have to take care. We will do the taking care for him.

Should newspapers over the country, generally, take this stand, it would sound the death knell of the fraudulent "patent medicine" industry. Imagine, if possible, a newspaper guaranteeing its readers against loss from taking "Pulmonol" or "Eckman's Alterative" for consumption, from taking "Swamp Root" or "Doan's Kidney Pills" for Bright's disease, from taking "Wine of Cardui" or "Lydia Pinkham's" for "female trouble," from taking Coutant's alleged cure for deafness, from using Plapao Pads for rupture, from taking any of the thousand and one wickedly exploited cures for cancer — imagine a newspaper that guaranteed its readers against "loss or dissatisfaction" carrying such advertisements! It isn't conceivable that any paper that had the interest of its readers sufficiently at heart to take the stand the *Tribune* has could, in the nature of the case, accept advertisements from fraudulent "patent medicine" concerns and quacks. Yet, as a moral principle, the new standard set by the New York *Tribune,* while so far in advance of the procession, is merely one of simple, elemental honesty. It is the stand that is taken by every honest man in business. The rapid change that is now taking place in the advertising world makes one optimistic. We believe that, before the present decade has passed, the position taken by the *Tribune* will be accepted as a matter of course by the majority of decent newspapers throughout the country. In the meantime, every right-minded citizen should throw the power of his influence behind those publications that are waging war against frauds and leading in the fight against those powers of evil that menace both public health and public morals. More power to the pen of the New York *Tribune.*

AN EARLY WORKER IN INDUSTRIAL HYGIENE

Nothing comes closer to actual humanitarianism than the prophylaxis of the ills caused by special occupations. Men must work to live, and if the work itself brings death, a vicious circle is created. Nov. 5, 1914, occurred the two hundredth anniversary of the death of Bernardino Ramazzini, the great leader in the study of the "hygiene of artificers." His name, like that of many noted medical men, is unfamiliar to most physicians of to-day. He was professor of the theory and practice of medicine in the historic school at Padua from 1682 to 1700. His chief work, "Health Preserved: I. On the diseases of artificers, which by their particular callings they are most liable to; with the method of avoiding them and their cure. II. On the distempers which arise from particular climates, situations and methods of life," is the work on which rests his claim to fame. This was translated, within a short time, into German, English, Dutch, Italian and French, and numerous editions were published. A German translation of his various medical works was published at Leipsic in 1828, and in 1912, F. Koelsch, chief of the factory inspection service in Bavaria, wrote a book describing Ramazzini's life and works. Professor Pogogeff of Moscow, founder of the museum of sociology there, organized an international exhibition of safety appliances in industry and for the prophylaxis of occupational diseases, to open in Moscow, November 5, but the war unfortunately put an end to all preparations. At Milan, however, the anniversary was celebrated with exercises at the Clinica delle malattie professionali, devoted exclusively to occupational diseases. The director of the clinic, Professor Devoto, delivered an address on Ramazzini's life and work before an audience of the working class and again before a medical audience, the address being published later in the *Lavoro,* a fortnightly periodical published by this enterprising clinic. A further honor to the great work of Ramazzini is the naming of the Italian periodical founded in 1907 by C. Biondi and L. Bovri, to advance the cause of social medicine, *Il Ramazzini.*

SAFETY IN THE MINING INDUSTRY

The report of the director of the Bureau of Mines for the year ended June 30, 1914, which has just appeared, shows a constant increase in the safety of workmen engaged in mining, though the loss of life is still great. During the year more than 3,500 men were killed and more than 100,000 injured in this industry. It is believed that one-half of the fatalities and three-quarters of the injuries were easily preventable, and much of the estimated twelve millions of money loss ultimately paid by the consumers should have been saved. Among the causes assigned for these casualties are mine explosions and mine fires, many of which were caused indirectly by electrical apparatus; the improper use of explosives and the use of improper explosives, directly or indirectly the cause of a large proportion of the fatal accidents, among which are accidents to shot firers; and injury to the health of the miners from poisonous gases given off by improper explosives, and from generally poor ventilation of the mines. The last is said to be true particularly of the metal mines, statutory provisions in regard to ventilation in the metal mining states being incomplete and inadequate, with no efficient system of ventilation generally in force. Although improvement has been made, there is still necessity for more extensive use of safety appliances. It is said that during the past five years through lack of such appliances more than 3,500 men have been killed and 20,000 seriously injured. To prevent injury to shot firers it is recommended that shots be fired by electricity from the outside of the mine and not in the present careless manner. The bureau has not only attempted to prevent coal-dust explosions, but also has devised means in the form of barriers loaded with stone dust for stopping such explosions after they have started, localizing them to the part of the mine in which they originate and thus saving miners in other parts. Improvements in explosives have also been made through the introduction of new types of low-temperature, quick-flame powders which may be used in the more dangerous mines. Instruction in mine safety and mine rescue work has continued, and the total number of miners trained by the bureau has now reached 25,000. First-aid stations have been established at hundreds of mines. The report says the states spend more money than the government for improvement in mining conditions, and the bureau complains that its work is handicapped by insufficient funds.

AID FOR DEVASTATED BELGIUM

In our news columns and in the London letters, we have mentioned frequently the pressing calls for aid to Belgium. In London a committee was formed, headed by Sir Rickman Godlee, to take up the care of needy physicians and surgeons in the little war-wrecked country. An appeal sent out by Professor Jacobs of Brussels describes conditions of destitution that are horrifying and almost unthinkable in their immensity. An American committee has been formed, consisting of many representative physicians and surgeons. Sunday, December 20, an organization meeting was held in New York. Dr. Howard Canning Taylor was elected secretary, and an executive committee was formed of which Dr. Frank F. Simpson, the treasurer, is a member. Dr. Bates, of the Commission for Relief in Belgium, has promised to distribute in Belgium without cost, food, surgical dressings, drugs, or instruments, and information is being gathered as to what is most needed. For the present, money contributions only are accepted. The treasurer, Dr. F. F. Simpson, Jenkins Arcade Building, Pittsburgh, to whom money should be sent, will publish each week a list of contributors. The cause is meritorious, the need pressing, the objects, brother physicians who are the unfortunate victims of circumstance. The American physician who helps in this crisis will aid to establish even more firmly the bond of brotherhood which has ever characterized men of science.

EXERCISE, BODY TEMPERATURE AND THE PULSE-RATE

Muscular exercise, even of a moderate sort, is attended by a number of conspicuous phenomena. The heart-beat becomes more rapid, the blood-pressure is raised, the temperature is elevated somewhat and pulmonary ventilation is increased. In bringing these useful functions into heightened activity a variety of factors are presumably involved. Ordinarily a rise in blood-pressure is attended with a slowing of the pulse; but after exercise the rise is accompanied by cardiac acceleration. The most important factor in the immediate quickening of the pulse-rate is doubtless the central nervous system, and presumably it operates by depression of the cardio-inhibitory center. The acceleration of the heart-beat does not cease immediately with the interruption of muscular effort, but commonly persists for a shorter or longer time. The return to the normal is almost always quicker in the trained than in the untrained person. Different physiologists have held more or less conflicting views respecting the cause of the persistent augmentation of the pulse. The Danish physiologist, Johansson, for example, has maintained that products of metabolism, arising as a consequence of exercise, are responsible for the quickening. Mansfeld has charged it to the rise in temperature of the blood flowing to the heart. Drs. Martin, Gruber and Lanman[1] of the Harvard Medical School argue that if persistent acceleration of the heart after exercise depends on the temperature of the blood, careful comparisons of body temperature and pulse-rate after exercise should show an interdependence between them. Moreover, the striking prolongation of the acceleration sometimes seen in untrained as compared with trained men should be correlated with a definite difference in the period of heightened body temperature. They have, therefore, made a careful comparison of the interrelation of the two factors in man with results which seem to show clearly that whatever may be the mechanism of the persistent cardio-acceleration of exercise, body temperature has little to do with it. Some other cause than the rise in blood temperature must be sought as the sustaining agent. It seems well established that variations in metabolic activity in man are accompanied by variations in heart-rate.[2] Whether heightened metabolic activity is the cause of an augmented pulse, or whether the two depend on a common antecedent stimulus, does not appear. Benedict and Cathcart[2] have noted that the metabolism, as measured by the oxygen absorption, continued high after exercise for periods comparable with those of augmented heart action. From the work of Martin, Gruber and Lanman, it also seems unlikely that the metabolic effects are directly dependent on an increase in the temperature of the blood. Other possibilities now need to be examined critically.

Medical News

(Physicians will confer a favor by sending for this department items of news of more or less general interest: such as relate to society activities, new hospitals, education, public health, etc.)

ILLINOIS

Roentgen-Ray Equipment Installed.—A complete Roentgen-ray equipment has been secured at a cost of about $2,000, and will be installed in the new wing of St. Joseph's Hospital, Elgin next week.

Military Surgeons Elect.—At the annual meeting of the Association of Military Surgeons of the State of Illinois held in Chicago, December 28, the following officers were elected: president, Lieut.-Col. Jacob Frank, Chicago, surgeon-general of Illinois; vice-president, Captain Arthur F. Wilhelmy, Decatur, and secretary-treasurer, Brig. Gen. S. C. Stanton, Chicago (reelected).

Hospital Faces Burden of Debt.—At a meeting of the board of directors of the Monmouth Hospital, December 15, the physicians presented a formal communication requesting that action regarding the proposed change of management be deferred for a period of one year. This action of the medical men directly opposes the recommendation of the finance committee. The hospital at present faces a debt amounting to about $3,000 and without any probability of immediate payment.

Chicago

Zones of Quiet.—A number of physicians appeared before the common council health committee, December 21, to present appeals for the establishment of zones of quiet around all hospitals.

Morals Board Appointed.—The names of thirty persons recommended to the mayor by the vice commission to aid his choice of the newly created morals commission included the following physicians: Drs. William A. Evans, W. J. Hickson, Sidney Kuh, Willis O. Nance, William Healey and Clara Seippel.

Low Mortality for Chicago.—The records of the health department for the year of 1914 show that the death-rate was 14.17 per 1,000. This is 3.6 per cent. less than the average yearly rate for the last decade and 6.2 per cent. less than the rate for the previous year. The chief reductions are in deaths from typhoid fever and from infantile diseases.

Polish Physicians Meet.—The Chicago Polish Medical Society held its annual meeting December 18, and elected Dr. Wladyslaw A. Kuflewski, president; Dr. Thaddeus Z. Xelowski, vice-president; Dr. Alexander Pietrzykoski, secretary, and Dr. Stanislaus Boguszewski, treasurer. Resolutions were adopted to aid the widows and orphans of Polish physicians in Poland and a subscription list has been opened for this purpose by the secretary.

The Cost of Tuberculosis.—Dr. Theodore B. Sachs estimates that tuberculosis costs an economic loss of more than $30,000,000 a year in Chicago. The opening of the Chicago Tuberculosis Sanatorium in February, will, he hopes, tend to reduce this loss by the reclaiming of many victims. The institution will have, at its opening, a capacity of 650 beds and by the end of the year the capacity will be increased to 950. It is provided with a maternity division, a department for children, a nursery, open air housing and comprehensive laboratories. The institution is located on a tract of 160 acres of land at Peterson, Crawford and Bryn Mawr avenues, and already has about 35 buildings, one of which has a frontage of 1,000 feet.

INDIANA

New Societies Organized.—The Indianapolis Pediatric Society has recently been organized with Dr. James H. Taylor as president, and Dr. E. B. Mumford, secretary.——Kendallville Medical Society was recently organized with Dr. Cyrus A. Gardner, president, and Dr. Harold O. Williams, secretary-treasurer.

Clinic at Anderson.—Physicians of Anderson met with a committee from the Anderson Council of Women, December 15, to confer regarding the advisability of establishing a free clinic in Anderson. There was no question regarding the necessity of the clinic, but its site was discussed and eventually left to a committee of six to investigate and report at a meeting January 6.

Personal.—Dr. Albert C. Kimberlin, Indianapolis, fell December 17, spraining his ankle and probably fracturing bones of his left foot.——Dr. Blanchard B. Pettijohn, Indianapolis, has resigned his commission as first lieutenant of the Medical Corps, Ind. N. G.——Dr. Tiffin J. Shackelford, Kokomo, who has been seriously ill in Chicago, is now convalescent at Muncie.——Dr. Frank L. Truitt has been elected medical director of the Reserve Loan Life Insurance Company, Indianapolis.——Dr. Richard A. Poole, coroner of Marion County, has appointed Drs. Paul F. Robinson, Edwin S. Knox and Herbert T. Wagner as deputy coroners.——Dr. Harry M. Hosmer, Gary, who met with an accident December 11, which it was thought would result in the loss of both eyes, is convalescent and will regain his eyesight.——Dr. Augustus L. Marshall, superintendent of the Indianapolis City Dispensary, suffered an electric shock and burns of the right hand, December 15.——Dr. Thomas L. Sullivan, Jr., has been appointed superintendent of the Indianapolis City Hospital.——Dr. Lee M. Barney, formerly of Elkhart, but more recently of Miami, Fla., has been awarded damages of $41,500 from the casualty companies on account of the loss of sight from a chemical explosion which occurred while he was making experiments in his laboratory.——Dr. A. Golding Chittick, Frankfort, has been appointed health officer, vice Dr. George W. Brown, resigned.

Two Units of New City Hospital Opened.—Two units of the new Indianapolis City Hospital are now partly in use. They represent the most modern type of hospital construction and embody several features which are unique. The mural decorations previously mentioned (The Journal, Dec. 5, 1914, p. 2049) are in part completed. The panels painted by Mr. T. C. Steele for the men's ward are of the best type of American art. Mr. Otto Stark has completed the "festival of toys" for the children's ward; a rising young colored artist, Mr. William Scott, has done an immense amount of work in the corridors. The value of these decorations can be calculated only in the pleasure which thousands of sufferers will derive from them. The cost of the two Burdsal units, approximately $350,000, is a monument to the economy of the administration. All floors are built with subfloors, making possible instantaneous access to heating, ventilating and plumbing apparatus. This innovation is a move toward future economy that will be a reminder of the forethought which planned it. The entire cost of the many feet of mural decorations has been slight, and the results are delightful. The hospital is inviting and pleasant, and the city authorities, headed by Mayor Bell, are being widely commended for this unique advance in hospital construction.

NEW YORK

Personal.—Dr. Garret K. W. Schenck, Rockaway Beach, has been appointed assistant chief surgeon of the Polyclinic Hospital, Manhattan.

Appropriation for Sanatorium Maintenance.—The board of supervisors of Tompkins County appropriated at its December 16 meeting $8,000 for the maintenance of the Meany Sanatorium at Taughannock Falls. This sum, with the $2,800 left over from last year's appropriation, makes available $10,800 at the beginning of the fiscal year, February 1.

New State Sanitary Code.—The Public Health Council of the State Health Department has adopted regulations which will become effective on March 1. These regulations have the same force as a statute enacted by the legislature and make violation a misdemeanor. Among other things the code puts a ban on the common drinking cup, the common towel, the unclean barber cup and hair brush, spitting on the streets and in public buildings, and insists on special regulations of manicurists and chiropodists.

New York City

Personal.—Dr. Richard Derby, who has been in the American Ambulance Hospital, Neuilly, France, has returned to his home and will resume his work at St. Luke's Hospital.——Dr. John H. Parker, who has been ill with septicemia due to a glass wound of the knee, is reported to be improving.

Disinfection of Cars.—The Interborough Rapid Transit Company writes the health department that they have been studying the efficiency of various disinfectants and their conclusions coincided with those of representatives of the department who have questioned the value of disinfectants for car cleaning purposes. They have therefore arranged to discontinue the use of disinfectants for this purpose, but are making an effort to cleanse cars by mechanical means and frequent airing.

MEDICAL NEWS

Decrease in Street Car Accidents.—There was a marked decrease in the number of street car accidents during the month of November, 1914, as compared with the same period of 1913. The number of persons killed in November, 1913, was 31, against 18 for November, 1914. The total number of accidents for November, 1913, was 3,557, while for November, 1914, it was 3,153. The falling off in the number of accidents is attributed to the near-side stop of street cars which went into effect on November 1.

Campaign Against Habit-Forming Drugs Progresses.—The campaign against illegal sellers of drugs is being energetically prosecuted. Within the space of three days three sources furnishing large amounts of narcotics have been located. The largest supply seized in years was taken on December 21 on the lower East Side. It was valued at $10,000 and included 150,000 pills and 37 boxes of powder. At about the same time it was learned that steamships from Liverpool were bringing over supplies of drugs and a search of the *Adriatic* which had just docked was found to have brought 100 small cans of opium selling at $50 per can. In the Harlem district six arrests have been made of persons selling cocain to schoolchildren; these individuals were held in bail for amounts from $500 to $2,500.

OHIO

State Board Election.—At the annual meeting of the Ohio State Board of Health held in Cleveland recently, Dr. Henry T. Sutton, Zanesville, was elected president; Dr. William T. Miller, Cleveland, vice-president.

Personal.—Dr. George W. Crile, Cleveland, has started for Europe for work with the American Ambulance, Paris.——Dr. William H. Wood, Smithfield, was operated on recently in Chicago for the removal of a cataract.——Dr. Alexander Hitchcock, Port Clinton, is reported to be seriously ill as the result of a cerebral hemorrhage.——Dr. W. T. Barger, Cleveland, has accepted a permanent position on the medical staff of the Jackson Health Resort, Dansville, N. Y.——Dr. H. E. Ward, Custar, is reported to be seriously ill at his home as the result of an automobile accident.

Antituberculosis Items.—R. G. Patterson, secretary of the State Antituberculosis Society, at a meeting of the local society at Chillicothe, recommended the erection of a district hospital with a capacity of fifty beds at an expense of $50,000.——Plans are in consideration for the erection of a division to the Butler County Tuberculosis Sanatorium which will allow the accommodation of at least twenty-five more patients and an expense of not more than $3,500.——Springfield Lake Sanatorium for Tuberculosis, erected by Summit, Portage, Mahoning, Stark and Columbiana counties, near Akron, at a cost of $280,000, was formally opened January 1. The institution will accommodate 150 patients.

Health Federation Formed.—For the support of legislation designed to promote public health and oppose measures deemed to be harmful, the Ohio Public Health Federation has been organized, the members of which are the Ohio Society for the Prevention of Tuberculosis, the Ohio State Medical Association, Ohio State Eclectic Medical Association, Homeopathic Medical Society of Ohio, Ohio State Dental Society, Ohio State Pharmaceutical Association and the Ohio State Veterinary Association. Heads of the state departments which have public health functions will cooperate with the federation. The State Board of Health, State Blind Commission, State Medical Board and the State Board of Pharmacy are so represented. The following are officers of the federation: president, Dr. Willard B. Carpenter, Columbus; secretary, Prof. Edward Spease; assistant secretary, G. V. Sheridan; and treasurer, Dr. John H. J. Upham, Columbus.

GENERAL

Lecture at Army Medical School.—Dr. Harvey Cushing, professor of surgery in Harvard University, delivered an illustrated lecture on "The Portraits of Vesalius," on the evening of December 29 at the Army Medical School, Washington.

National Leprosarium.—Surgeon-General Rupert Blue, U. S. P. H. S., has recommended to the commerce committee of the house of representatives the establishment of a national leprosarium, under the control of the public health service. There are now 146 cases of leprosy on record in the United States.

Eastern Pediatrists Hold Election.—At the annual meeting of the New England Pediatric Society held in Boston, December 4, the following officers were elected: president, Dr. Edward M. Buckingham, Boston; vice-president, Dr. Edmund F. Curry, Fall River, Mass., and secretary-treasurer, Dr. Richard M. Smith, Boston.

Southwestern Practitioners Meet.—At the annual meeting of the Southwestern Medical and Surgical Association held in El Paso, Tex., December 11 and 12, the following officers were elected: president, Dr. John E. Bacon, Miami, Ariz.; vice-presidents, Drs. Jesse R. Gilbert, Alamogordo, N. Mex., and James Camp, Pecos, Tex.; secretary-treasurer, Dr Charles P. Brown, El Paso, Tex. El Paso was selected as the place of meeting for next year.

Indian Service Notes.—Dr. J. A. Murphy, medical supervisor, Phoenix, has gone to Sacaton, Pema Agency, for several weeks.——A new hospital for the Indians of northeastern Minnesota, the cost of which was provided for in the last Indian appropriation, is to be erected at Cloquet, Minn.——Dr. Frank J. McKinley, Pala, Cal., has been transferred as superintendent at Schurz, Nev.——Dr. Peter A. Slattery has been transferred from Fort Bidwell, Cal., to Acomita, N. Mex.

Tri-State Medical Society Meeting.—At the annual meeting of the Tri-State Medical Society of Arkansas, Louisiana and Texas, held at Shreveport, La., December 8 and 9, the following officers were elected: president, Dr. William G. Hartt, Marshall, Tex.; vice-presidents, Drs. Edwin L. Beck, Texarkana, Tex.; Oscar Dowling, Shreveport, La., and Edward H. Martin, Hot Springs, Ark.; secretary-treasurer, Dr. Jacob M. Bodenheimer, Shreveport, La. (reelected). The next meeting will be held in Marshall, Tex.

Canal Zone Physicians to Meet in San Francisco.—The Medical Association of the Isthmian Canal Zone announces that at the November meeting of the society it was decided to hold an extraordinary session at the Panama Pacific Exposition, San Francisco, some time during the medical period, and preferably about June 14, and the society requests that all former and present members will endeavor to assemble at San Francisco during that week, prepared to support those in charge of the session. Members living near San Francisco are asked to communicate with the officials and express their intentions as regards attendance.

Bequests and Donations.—The following bequests and donations have recently been announced:

St. Louis Medical Society, $42,000 left in trust by the administrators of the estate of Mrs. Francisca Bartscher, mother of the late Dr. Hugo Bartscher, as a memorial of her son.

For the relief of the aged poor of Indianapolis, the bulk of the estate valued at $250,000, by the will of Mr. William L. Higgins.

German Hospital, New York, $5,000 by the will of Joseph Kuder.

St. John's Guild, New York, for the benefit of the Sea Side Hospital, $10,000 by the will of Laura V. Rhinelander.

St. Luke's Hospital, New York City, and Society for the Relief of the Destitute Blind, each $5,000 by the will of Miss Augusta Jones.

Maimonides Hospital, Chicago, $2,000 appropriated by the Federated Orthodox Jewish Charities.

Chicago Lying-In Hospital, $10,000, the proceeds of an opera performance at the Chicago Auditorium, December 18.

The Lane Lecture for 1915.—Dr. Frank Billings, Chicago, has been selected to deliver the Lane Lecture for 1915. He is the fifth American to be so honored. A list of the previous lecturers follows:

1896. Sir William Macewen, M.D., Regius Professor of Surgery, University of Glasgow. "Surgery of the Brain."

1897. Christopher Heath, F.R.C.S., Professor of Clinical Surgery, University College, London. "Congenital Malformations, Aneurism, and other Surgical Topics."

1898. Thomas Clifford Allbutt, M.D., F.R.S., Regius Professor of Physic, University of Cambridge, England. "Diseases of the Heart."

1899. Nicholas Senn, M.D., Ph.LL.D., Professor of Surgery, Rush Medical College, Chicago. "Topics in General Surgery."

1900. Sir Michel Foster, K.C.V., D.C.L., Professor of Physiology, Cambridge, England. "History of Physiology."

1901. Sir Malcolm Morris, F.R.C.S., Edinburg, M.R.C.S., England; Surgeon, Skin Department St. Mary's Hospital, London. "Social Aspects of Dermatology."

1902. Sir Charles B. Ball, M.Ch., F.R.C.S., Regius Professor of Surgery, University of Dublin. "Diseases of the Rectum."

1903. Oscar H. Allis, M.D., Philadelphia, Pa. "Dislocations and Fractures Involving Larger Bones."

1904. William H. Welch, M.D., LL.D., Professor of Pathology, Johns Hopkins University, Baltimore. "Infection and Immunity."

1905. Sir Patrick Manson, K.C.M.G., F.R.S. "Tropical Diseases."

1906. John C. McVail, M.D., D.P.H., Cambridge, Glasgow. "Practical Hygiene, Epidemics and Preventive Medicine."

1910. Reginald Heber Fitz, M.D., LL.D., Hersey Professor of Theory and Practice of Medicine, Harvard University, Boston. "A Consideration of Some Features of the Lymphatic System."

1911. E. Fuchs, Professor of Ophthalmology, University of Vienna. "Importance of Ophthalmology in Its Relation to Systemic Disease."

1913. Edward Albert Schaefer, Professor of Physiology, University of Edinburgh. "Internal Secretion."

FOREIGN

Grants for Scientific Research.—The Austrian Academy of Sciences has given Prof. Wagner v. Jauregg $1,250 to finance further his research on the etiology of goiter; Professor Honigschmid of Prague was also given a grant of $613 to continue his studies of the atomic weight of the radium elements, and Professor Netolitzky of Czernowitz $375 to continue his study of the history of foodstuffs.

Prophylaxis of Plague in Italy.—The authorities at Naples have ordered that in view of the fact that various ports in the basin of the Mediterranean have lately become foci of bubonic plague, all ships must take strict precautions and use guards, etc., to prevent rats getting ashore from the ships. None can anchor less than 5 meters from the dock.

Comparison of Casualties at Football and Bull-Fights.—The *Medicina Contemporanea* of Lisbon, November 15, quotes a Spanish daily which compares the casualties during the last three months at football in the American university teams (fourteen dead and 175 injured) with the casualties at the bull-fights in Spain during the same period. "The bull-fights make a better showing, and it is still better," our exchange adds, "when we consider that football often entails a predisposition to lung and heart disease."

Deaths in the Profession Abroad.—The death is reported of Prof. Charles Périer of Paris, president of the Académie de Médecine, aged 78.——The cable reports the death of Alfred Fournier, one of the leading [illegible] world, aged 82, professor of dermatolo [illegible] at the University of Paris from 1863 until he reached the age limit. To the medical mind, "Fournier" spells "syphilis," as his works have been the text-books for more than one generation, and his methods were long the basis of treatment in all civilized countries.

WAR NOTES

Red Cross Seals in Germany.—Red Cross seals are being sold extensively in Germany. There is both a five- and a ten-pfennig seal.

Woman Physician Decorated for Bravery.—The *Deutsche medizinische Wochenschrift* states that the wife of the Vienna surgeon, A. Lorenz, accompanied him to the front as his assistant, and has recently been decorated by the emperor, receiving the gold Order of Merit with crown and the bravery medal.

Human Documents from the War.—The stories told by the wounded soldiers who have been cared for at the Charité hospital at Berlin form an interesting little volume of adventures and experiences — *Kriegsdokumente* — which is being sold by the G. Thieme firm at Leipzig for the benefit of the families of the wounded.

Minor Inconveniences of the War.—In Germany the wounded have frequently been carried past their homes or not carried far enough. The Rhinelanders have been taken far inland, and the Berliners left in the Rhineland, Bavarians taken to northern Germany and so on. The Red Cross has made a vigorous protest against this, and pleaded that the interests of the individual wounded should be regarded more than the train schedules, and the condition is being remedied.

Certain Quack Advertisements in Berlin Forbidden During the War.—The authorities have decreed that as long as the war lasts no newspaper or periodical published in Berlin or the province of Brandenburg is to be allowed to publish the advertisements of persons claiming to cure what are generally known as venereal diseases or their consequences or advertisements of articles or methods of treatment directed to the relief or cure of such. The decree does not apply to regularly registered physicians.

Medical Students at the Front.—Emergency examinations have been held in Germany to permit students who had nearly completed their medical course to take up active duty. The *Medizinische Klinik* states that about 2,250 medical students have thus blossomed out as physicians, and all but 750 have been distributed among the land and sea forces. The total number of physicians in the German empire has thus been summarily increased by about 7 per cent. The regular examinations will have to be taken later.

Medical Meetings at the Front.—The German army surgeons at various points at the front gather once or twice a week for general discussion, and the reports of these informal "army-medical evenings" are published regularly in our German exchanges. Especially in Belgium, the German and Belgian physicians gather frequently for these professional "smokers." In the home zone the meetings of different medical organizations are generally merged into one meeting, as there are so many gaps in the ranks.

Alcohol Among the Soldiers.—The prohibition of alcohol among the German troops has been partly lifted, as it was realized that the cold and damp bringing on intestinal trouble in many soldiers caused them to long for the transient warmth and subjective relief afforded by a drink of liquor. So it was decreed that if, under such circumstances, liquor was to be allowed the men it should be in the form of red wine. The temperance movement in the army, the authorities reaffirm, will otherwise be promoted in every way.

Committee to Aid Belgians.—An appeal made by Dr. Charles Jacobs of Brussels for aid for civilian physicians, pharmacists and patients in Belgium, has resulted in the organization of a committee of American physicians for the purpose of aiding those requiring help. The Commission for Relief in Belgium will deliver supplies, and in order to insure quick delivery it has been arranged that all shipments by the Committee of American Physicians will be made in boxes painted yellow. The color scheme adopted is designed to facilitate the safe passage of articles across the sea and through various countries. Subscriptions to the fund should be sent in the form of a check or postal order, made payable to Dr. Frank F. Simpson, treasurer, 7048 Jenkins Arcade Building, Pittsburgh, Pa.

Contributions to Fund for Belgian Physicians.—Dr. F. F. Simpson, treasurer of the Committee of American Physicians for the Aid of the Belgian Profession, announces that for the week ending December 26, the following contributions have been received: Union Trust Co., banking facilities; Sterrett and Acheson, attorneys, professional services; F. O., $25; F. H. M., $100; F. F. S., $100; S. P., $25; G. C. S., $5; S. A., $20; E. W., $25; B. L., $10; T. E. S., $20; T. L. S., $25; R. S. E., $10; M. W. R., $10; W. A. P., $25; M. C. S., $5. Total, $405.

Deaths in German Army.—In the four weeks ending November 24, the *Münchener medizinische Wochenschrift* had given the names and titles of sixty-seven German physicians or medical students who had died or been killed at the front. Some died from infection contracted in tending the wounded. In the latest compilation, twelve of the forty-two names are listed as "stud. med." or "cand. med.," and most of them as *Kriegsfreiwilliger*, "volunteers." No lists of names are given in the French exchanges received, but some of our German exchanges publish within a laurel wreath the names of the members of the profession who have been wounded or are missing or have fallen or died otherwise at the front, as also all who have been awarded the iron cross for special gallantry under fire.

Quarters for the Wounded in Paris.—The *Presse Médicale* of November 19 gives the official list, with addresses, of the hospitals and other quarters in and around Paris arranged to receive wounded soldiers. Besides the four regular military hospitals and sixty-nine annexes, the Red Cross has 105 auxiliary hospitals, the Women's Union eighty-six, the Association des dames françaises 100, there are the twenty-five regular municipal hospitals and a long list of convalescent homes. The only independent hospitals, that is, under the direct control of the war department, are the English Hospitals with two annexes (one in the Hotel Astoria) and the American Hospital. The various auxiliary hospitals include of course many private residences, schools, colleges, casinos and stores, the Bon Marché, the Magasins du Louvre, the Masonic Temple, club houses and fashionable hotels.

Financial State Aid for Women at Confinement.—The German parliament is now discussing ways and means to provide state aid for women at childbirth. The plan is to supply medical care and obstetric nursing free of charge and also a pension during the eight weeks following, and a small daily sum thereafter as long as the woman nurses her babe, up to the end of the twelfth week after delivery. It is estimated that if this scheme goes through as proposed by the Bundesrat the expense will be about half a million dollars a month. "This expense is justified," the speakers said, "from the standpoint not only of the aid to the head of the house who has been called to the colors and has had to leave his wife unprovided for, but also from the standpoint that the losses in human lives sacrificed in the war make it the imperative duty of the state to care for the coming generation and promote its healthy growth in every way, even from its first entrance on the scene."

Medical Schools Abroad During the War.—Our exchanges mention resumption of the work of the medical schools to some extent, as many of the professors are too old for active service at the front and are keeping up their courses; but the academic halls are nearly deserted except where they have been converted into hospitals for the wounded. The Italian universities offer hospitality to students from other countries, the *Policlinico* saying that there can be no infringement of the obligations of neutrality in inviting students from other countries, including those from Russia, Servia and Japan, to whom the universities of Germany and Austria are now closed. The editorial deprecates "the prevailing custom of regarding laboratory achievements as the key that opens the door to academic positions. Minute study of some one small subject does not fit a man to be a successful instructor as much as broad culture and a synthetic vision of the whole field and its correlation with the other fields of knowledge." The medical schools in Switzerland have long been frequented by numbers of students from Russia and the Balkan states, and the proportion is still large.

Rye Must Be Mixed with Wheat Flour in Baking Bread in Germany.—According to our German exchanges just received, the decree of the Bundesrat regulating the consumption of flour went into effect December 1. It provides that no bread shall be baked henceforth from pure wheat flour. The bread must contain at least ten parts—by weight—of rye flour to ninety parts wheat flour. Rye bread offered for sale must be made with at least five parts potato flour to ninety-five parts rye flour. The baker can increase the proportion of potato flour if he wishes, but bread with more than five parts potato flour must be marked with the letter "K" (*Kartoffel*, "potato"). If there is more than twenty parts potato flour, the figure must be added to the "K." The feeding of rye and wheat grain or flour to domestic animals is strictly prohibited. Wheat flour is to be sold without admixture of rye. It is left to the baker to do the mixing. The decree specifies that the wheat flour must be bolted at least to 75 per cent. and rye flour 72 per cent. The term bread includes loaves, rolls, etc., but not cake or zwieback. The *Medizinische Klinik* comments on this regulation that "pure" wheat flour is seldom or never met with, as what is offered as such on the market almost invariably contains more or less of other grains. It continues: "The physician will not find that the new regulation interferes with his dietetic management of his patients as, if wheat bread is particularly needed for a patient, he can have it baked in the house or substitute cake or zwieback for loaf bread. The small admixture of rye in the bread or of potato flour in rye bread are of no consequence, it adds, from the medical point of view. What is important is to know that pure wheat flour can be bought as such, and that zwieback and similar light biscuits and cakes for the use of the sick are not affected by the decree which has only the commercial bakeries in view. The carbohydrate proportion, the starch and dextrinized substances in the bread, are not modified by the change, that is to say, there is no modification in the most important elements of the bread from the economic standpoint. There is scarcely any reduction in the elements representing the calorie value of the bread; the modification is almost exclusively in the proportions of the gelatinoid or albuminoid elements and in the proportion of the cellulose refuse. Of the three kinds of flour concerned, wheat flour contains the largest amount of protein and the smallest amount of cellulose, and potato flour the reverse. The bread will, therefore, be poorer in protein and contain more cellulose, but the change is so slight that it is negligible from the economic standpoint."

LONDON LETTER

London, Dec. 11, 1914.

The War

THE EXPLOSIVE EFFECT OF BULLETS

The ghastly effects sometimes produced by the modern rifle bullet, in contrast to the usual small aperture of entrance and exit and rapid healing, is still causing discussion as to the use of explosive bullets. Confusion arises from failure to distinguish between explosive effects produced by a legitimate bullet and the effects of an explosive bullet. That the pointed modern bullet, which differs little in the armies of all the combatants in the present war, may produce under certain conditions explosive effects has been abundantly shown. Mr. G. H. Makins, consulting surgeon to the expeditionary force, points out that these depend on two factors—high velocity and instability in flight—of which the latter is much more important. The effect of the former is principally shown by extensive comminution of bones when struck at a right angle. According to Mr. Makins, the instability of flight and tendency of the bullet to revolve around a transverse axis give it a capacity for wounding the soft part greater than that of any expanding or soft-nosed bullet. Unless impact with the body takes place by almost the exact tip, a rapid revolution of the bullet on its axis occurs and the bullet is driven sideways through the tissues, producing an extensive aperture of exit.

NEUROSES AND THE WAR

A certain number of cases of hysteria, traumatic and otherwise, are being observed in invalided soldiers. They appear to be due to a combination of factors such as fatigue, hunger, strain of responsibility and exposure to repeated explosions. In some cases autosuggestion appears to play a part. Thus a Belgian soldier was hit on the back by a heavy wooden sleeper blown against him by the explosion of a shell. He was knocked down half unconscious from shock and pain, and was brought to this country with paralysis of the left leg which on examination proved to be typically hysteric. In other cases, autosuggestion does not appear to play a part. Thus a British officer strained his right side in carrying a heavy wounded man. Three days later he noticed that he was dragging his right foot and that his right arm was weak. He was found to be suffering from hysteric hemiplegia.

THE OUTBREAK OF TYPHOID FEVER IN BELGIUM AND NORTHERN FRANCE

This outbreak was mentioned in a previous letter. It appears to be due to the drinking of unsterilized water by the Belgian troops. In the area flooded to bar the way of the Germans, the floods have emptied the cess-pits and middens and spread their contents far and wide. Moreover, many corpses are floating in the water. According to the principal medical officer of the Belgian troops, the reports of the outbreak have been exaggerated and there are only 120 cases among the soldiers. However, from twenty to thirty per day arriving at Calais have been reported. A traveler who has returned from a town in the southeast corner of Belgium states that it was being converted into an immense hospital to deal with convalescent typhoid cases, of which 1,600 had already arrived and preparations were being made for 4,000 more. So far there have been very few cases among the British troops—less than 200 in two and one-half months, and of these only five occurred among men who had been properly inoculated against the disease.

HOSPITALS AND THE WAR

By the erection of new hospitals as well as by the extensive accommodation offered in existing hospitals, ample accommodation is being provided for the wounded. To take only one example, the London Hospital has offered as many as 500 beds for the wounded soldiers and sailors, of which only about half have so far been required. This hospital has also under consideration the dispatch to France of a contingent of surgeons, physicians, nurses, dressers, roentgenographers and others sufficient to staff a hospital there. By such an arrangement most members of the hospital staff would be able to take a term of service with the contingent. Should the War Office desire, such a contingent will be immediately forthcoming. The base hospitals in France are well provided with consultants of all sorts. Eminent surgeons, physicians, ophthalmologists, and others have freely given their services. Among the latest are Sir Berkley Moynihan and his assistant, Mr. L. R. Braithwaite, who have gone as consultants in abdominal surgery.

THE EFFECTS OF THE WAR ON CIVILIAN PRACTICE

The war has effects on civilian practice, some of which are curious. There is a great falling off of office work, especially in consulting circles. The reason is that patients who read about the dreadful injuries of war think less of their own ailments. Hysteric and neurotic persons have now something to think about outside themselves. Even in the case of real ailments in which there is no urgency for treatment, such for example as hemorrhoids, patients trouble less about their symptoms and postpone operations. Another factor, no doubt, is the financial stress which leads to curtailment of expenditure. On the other hand, the profession has been financially benefited in some directions. The great demand for army surgeons has caused a falling off in the applications for junior institutional appointments, and increased salaries have to be offered. In one case the salary offered was doubled, and yet the advertisement still appears.

THE WAR AND CRIME

Another curious effect of the war is a great diminution of crime. The earlier closing of saloons, announced in a previous letter to The Journal, is one of the factors. At the present sessions of the Central Criminal Court there is no charge of murder or manslaughter. In an interview, a London magistrate has expressed himself as follows: "The criminal is a patriot. There is a genuine feeling of public spirit to be noticed to-day among those whom we call the criminal classes. Not only the graver forms of crime—those attended by violence, for example—but the most casual type of offense is less common than in the time of peace. The same moral improvement of the criminal was noticed—though not in so marked a degree—during the South African War. The criminal, like the honest citizen, is impressed by the war conditions, which make it every man's duty to give as little trouble as possible." The suffragettes have discontinued their agitation, and thus another source of crime is abolished.

THE EFFECTS OF THE WAR ON THE DRUG SUPPLY

This was the subject of discussion at the Pharmaceutical Society. Prof. H. G. Greenish dealt with the question of crude drugs, and expressed the opinion that the number of medicinal plants at present under cultivation in different parts of the British Empire might be very considerably increased. Was it not possible to find a substitute for a drug, the supply of which had been seriously curtailed as a result of the war? Necessity might compel us to search for parallel drugs, and, in the event of such not being forthcoming, to prosecute the cultivation of the drug we required in one of the divisions of the empire, and so render ourselves less dependent on sources of supply that might at such times as the present fail altogether. Mr. J. C. Umney said the action of the government in connection with a drug supply advisory committee in framing an effective schedule of contraband of war had done much to prevent clearance of existing stocks, and so protected the interests of our land and sea forces as well as those of the civil population. The action of the government, by their inquiries and legislative power of acquisition, had leveled prices from the range of fancy to fact in the short space of two or three weeks. Mr. C. A. Hill, referring to the manufacture of synthetic drugs, said we could not expect to build up in a few months an industry which had taken forty years to develop in Germany. One of the great difficulties was that each product depended on others, the raw materials of one synthetic substance being a by-product in the manufacture of another. It would not pay to put down an expensive plant for the manufacture of a few products, the whole consumption of which was only a matter of perhaps hundredweights, but it would pay a factory which could turn out a hundred products each with a consumption of some hundredweights per annum. Mr. F. W. Gamble reviewed the position with regard to serums and vaccines. Since the outbreak of war, large quantities of typhoid vaccines had been supplied to the War Office, and there had been a heavy demand for calf-lymph, antisepsis vaccine and tetanus antitoxin.

Alive After a Fall of 115 Feet

The case of a man who survived a fall of 115 feet furnishes a record. An inquest was held on a builder's signalman who died as the result of the collapse of a derrick staging in a gale. His companion who had fallen 115 feet on to hard concrete survived, and the inquest was adjourned for his attendance.

PARIS LETTER

Paris, Nov. 19, 1914.

The War

WAR AND INSANITY

It is well known that during the war in Manchuria the number of cases of insanity, especially in the Russian army, were very great. Therefore, at the beginning of the present war, measures were taken to provide against the danger of an outbreak of insanity, and it was agreed that, in view of the probable number of cases, a special asylum should be reserved for all the unfortunates demented by war. Experience has shown that these apprehensions were exaggerated. Cases of insanity caused by the war among civilians or soldiers are very rare at present. They can be divided into four classes: There were, at the outset, some cases of insanity clearly due to alcoholism; also some cases of latent general paralysis which developed under the strain of sudden emotion, and likewise cases of melancholia. What has been feared especially, however, in view of the experience of the war in Manchuria, has been the fourth class of cases —those induced by the inevitable fatigue of the campaign. These fears have not been justified for such cases have been very rare, chiefly because the nutrition and hygiene of the troops are incomparably better than were those of the armies in Manchuria.

THE USE OF TETANUS ANTITOXIN

By order of the minister of war, a commission consisting of Dr. Roux, director of the Institut Pasteur, Dr. Vaillard, medical inspector-general, and Dr. Chavasse, director-general of the sanitary service of the group of armies, has been organized to study the best method of utilizing the available supply of tetanus antitoxin. Since the injection should be made as soon as possible after the wound the commission proposes the following measures:

1. All the ambulances and hospitals near the front and also the sanitary trains shall be supplied in the first place.
2. Delays and losses are to be avoided by sending consignments of serum expressed to their destination.
3. Since wounds of the soft parts rarely cause tetanus, injections of serum are to be made by preference in cases in which wounds affect the bones or are manifestly soiled or contain foreign bodies.
4. Preventive injections are to be given in the ambulance or in the hospital near the front. When, on account of the great number of the wounded, the physicians near the front have not the time to do this, the injections should be made in the more distant hospitals or in the sanitary trains which should always be provided with supplies necessary for dealing with these cases.
5. The application of these measures is to be facilitated by tagging the patient with an individual record slip attached to his clothes in which the physician who made the first dressing shall mention whether or not he has made the preventive injection. This tag is to be carefully preserved.
6. When the physician believes that an infected wound may still be liable to tetanus, he should make a second injection several days after the first and sometimes a third after the second. To avoid the danger of anaphylaxis, it is best to have no longer interval between the injections.
7. In the cases of outspoken tetanus, intravenous, intraspinal or intracerebral injections should be used. The commission recommends that the physician make sure that the patient has never received a therapeutic serum injection (antidiphtheritic, antidysenteric, etc.). If he has, in order to avoid anaphylaxis, Besredka's method of subintrant injections should be followed, that is, the serum should be diluted to one-tenth strength and 1 c.c. injected into a vein; four minutes afterward, 3 c.c.; two minutes afterward, 5 c.c.; fifteen minutes afterward, pure serum either into the vein or into the spinal canal.
8. The commission emphasizes that strict and immediate antisepsis of wounds is one of the best means of avoiding tetanus.

THE PROPHYLAXIS OF TYPHUS IN THE ARMY IN THE FIELD

Dr. Charles Nicolle and his collaborators of the Institut Pasteur de Tunis have shown by experiments confirmed by American physicians in Mexico (The Journal, March 23, 1912, p. 873, and April 20, 1912, p. 1198) that lice are the agents of the propagation of exanthematic typhus. The prophylaxis of typhus based on this important discovery has given very remarkable results. Typhus, which was endemic in Tunis and which has claimed a large number of victims among the native population each year, has almost completely disappeared. The number of cases, which was 836 in 1909, fell to 22 in 1912. The only measure taken was a systematic destruction of lice about the patients and in their environment.

November 9, Professor A. Laveran, before the Académie des sciences, called attention to the special interest of these facts to-day. Exanthematic typhus is par excellence a disease of armies in the field. It was formerly called "camp-fever," "malignant fever of armies" and "war plague." The list of deadly epidemics of typhus which have raged among armies in the field, is a long one. Thus, during the Crimean War (1855-1856) typhus made great ravages among the French and English armies. The soldiers, for protection against the cold and the projectiles of the enemy, dug themselves covered pits where contagious diseases spread with great facility. To-day, because of the progress in artillery, the use of trenches has become general. During the great battles of the Marne and the Aisne, trenches, covered or not, took on such importance that these battles are justly compared to sieges. Now, that the winter is coming on, the tendency of the soldiers to shut themselves up in molehills, as it were, is possibly increasing and if the germ of typhus were to be imported into the army, it might give rise to a disastrous epidemic. Is this importation possible? Laveran replies that it is, for exanthematic typhus has long been endemic in certain German provinces, especially Silesia. The treatment of phthiriasis in the soldier is always a necessary measure of cleanliness and hygiene. Under present conditions, it is the most efficacious measure that can be taken against exanthematic typhus.

SURGICAL INTERVENTION IN LESIONS OF THE NERVE TRUNKS OF THE LIMBS BY MILITARY PROJECTILES

November 10, Dr. Walther, *agrégé* professor at the Faculté de médecine de Paris and surgeon to the hospitals, read an interesting paper on this subject before the Académie de médecine. At the military hospital of Val-de-Grâce, Walther observed, in 502 wounded patients, twenty-seven cases of lesions of the nerve trunks, eighteen in the arm and nine in the leg. He operated in six cases. Generally, the anatomic lesions demonstrated during operation consisted of a very sharp compression of the nervous trunk by a thick solid mass of very hard cicatricial tissue much larger than would be supposed from the dimensions of the cutaneous scar. Indication for operation is often established by the intensity of pains. The operation can be performed very early, even before the complete cicatrization of the cutaneous wound if a large resection of this wound and the subjacent cicatricial tissue is made. When there is complete paralysis without pain, it is better to wait for the cicatrization of the wound, but if then no tendency to improvement under medical treatment is observed, it is better to operate early in order to avoid the aggravation of the lesions by compression from the retraction of the deep cicatrix. The operation is usually laborious. Walther recommends bathing the nerve constantly during the operation with warm isotonic, physiologic saline solution. An important feature of the operation consists in building up, above and below the nerve, two planes of normal tissues so as to avoid all probability of retraction of cicatricial tissue. This may almost always be done by adjusting a slip of neighboring muscle tissue, maintaining it in place by suture on the edge which does not pull on the nerve. The defect in the skin resulting from removal of the cicatrix may be very large and should be repaired by autoplasty so that the whole region is covered anew with supple and mobile tissue.

The results of these operations have been very satisfactory; the pains have disappeared immediately, though they generally reappear momentarily during the following days much attenuated. and of different characters; they cease completely after ten or fifteen days. In a case of paresis from compression of the median nerve, complete reestablishment of mobility was obtained at the end of twenty days. There has been no functional improvement as yet in the three cases of total motor paralysis.

Paris, Dec. 3, 1914.

HOSPITALS FOR SOLDIERS OF THE BELGIAN ARMY AND FOR COLONIAL SOLDIERS

A hospital of 200 beds for wounded Belgian soldiers, forming a complete separate service having its own entry, is to be installed at Paris at the Hôtel-Dieu. The great halls of the ground floor will hold the dressing-rooms and the storerooms, also a workshop for the preparation of warm clothes for the convalescents leaving the hospital. The wards for patients, officers' rooms, and the isolation-rooms will be on the two floors above. The medical and nursing staffs will be entirely distinct from those of all other institutions. At the entry will be placed a tablet bearing the inscription "Military Hospital Albert I Created by the City of Paris for the Wounded Soldiers of the Belgian Army." The court of honor will bear the name of "Court of Queen Elizabeth." The rooms of the hospital will be called by the names of Belgian cities: Brussels, Liége, Antwerp, Louvain, Malines, Namur, Dinant, Bruges, Ghent, Ostend, Nieuport, Dixmude, Ypres and Furnes.

Our wounded colonial soldiers are at present widely scattered. Placed among Europeans whose language they do not know, deprived of news of their families, with whom, since they do not know how to read or write, they cannot correspond, these soldiers are rapidly affected with melancholia, and physicians state that this mental attitude has a bad effect on their convalescence. It was thought that by placing these men together and facilitating the receipt of collective news from their homes, these disadvantages would be obviated to some extent. The installation of a special hospital for wounded colonial soldiers has therefore been proposed.

PRESERVED MEATS FOR THE ARMIES

November 23, Dr. Roux, director of the Institut Pasteur, read a paper before the Académie des sciences on means of preparing preserved meat for the armies, especially for the entrenched camp of Paris. The operation consists in placing in metal cans, 800 gm. of raw meat cut into pieces, 50 gm. of rice, 10 gm. of salt and 2 gm. of agar-agar. The cooking is done in an autoclave in three hours and the cans are then sealed. Dr. Roux admits that the method officially sanctioned by the war department is preferable, but it is also less expeditious, and speed is an important element under the present circumstances.

ANTITYPHOID VACCINATION IN THE NAVY

The minister of marine has just addressed to naval officers a circular letter making antityphoid vaccination obligatory in the navy, as it already was in the army. Vaccination is not to be performed on men protected by a previous attack of typhoid, those who present contra-indications, those who are to be on active duty immediately, or those who cannot be kept in one place for a sufficient length of time to permit the application of the entire course of treatment.

AID FOR THE STUDENTS OF LILLE

The vice-rector of the Académie de Paris has informed the dean of the Faculté de médecine de Paris that he may, at the request of students of the Faculté de médecine of the Université de Lille, authorize them to follow provisionally without payment of fees, the work corresponding to their year of studies and to use the library up to the time until they are able to resume their studies in Lille.

PROHIBITION OF ABSINTHE IN THE COLONIES

A decree has just forbidden the introduction, manufacture, sale or possession, for personal use or for sale, of absinthe and the similar liquors throughout the colonies and territories of western French Africa.

THE SALE OF THE RED CROSS STAMP

I mentioned in a previous letter (The Journal, Oct. 31, 1914, p. 1591) the creation of a special 15 centime (3 cents) postage stamp one-third of the price of which goes to the Red Cross. The sale of this stamp had realized, up to October 1, 120,000 francs (about $24,000). Still larger sales are hoped for.

TWO NEW HOSPITAL SHIPS

The Société générale des transports maritimes has decided to transform two of its boats, the *Aquitaine* and the *Boukkala*, into hospital ships. The society defrays all the expenses. One hundred and thirty beds are placed on the spar deck, which is arranged as a dormitory. The poop has been made into a refectory. The medical and nursing staff is lodged in the cabin. The two boats are now ready to receive wounded.

THE ACADEMY OF MEDICINE ON THE SUBJECT OF THE PROHIBITION OF ALCOHOL

November 24, the Académie de médecine unanimously voted its approval of the action of the czar of Russia in forbidding the manufacture and sale of alcoholic drinks.

PERSONAL

Among the numerous members of the medical profession who have received the decoration of the Legion of Honor for their practice in the war are Dr. Proust, agrégé of the Faculté de médecine de Paris and surgeon of the hospitals and Dr. Victor Pauchet, professor at the Ecole de médecine d' Amiens. The former was mentioned in an order of the day for having displayed remarkable devotion and energy in the organization of sanitary service August 22-26, and for operating on the wounded under the fire of the enemy. Dr. Pauchet was decorated with the following official mention: "A surgeon of great scientific renown who, by his inexhaustible activity and devotion above all praise has under the most difficult circumstances saved the life of a great number of dangerously wounded."

Death of Dr. Léon Vaillant

Léon Vaillant, doctor of medicine and of sciences, has just died in Paris, aged 80. He was formerly professor at the Faculté des sciences de Montpellier and honorary professor of the Museum of Natural History at Paris, and member of various scientific societies.

Marriages

Rembert James Coney, M.D., Eutawville, S. C., to Miss Daisy Katherine Minahan of Charleston, S. C., at Orangeburg, S. C., December 15.

Karl Osterhaus, M.D., Washington, D. C., to Miss Elizabeth Oxley Currie of Winslow, N. S., at New York City, December 2.

Robert Hamilton Bishop, Jr., M.D., Saranac Lake, N. Y., to Miss Constance Mather of Cleveland, Ohio, December 5.

Alfred Magnus Kendahl, M.D., Jasper, Minn., to Miss Lillian Rosina Natzke of Pipestone, Minn., December 12.

Arthur Flournoy Jackson, M.D., to Miss Margaret Christy Tupper, both of Honolulu, H. I., November 20.

Junius Hardin McHenry, M.D., New York, N. Y., to Miss Amy DuPuy of Pittsburgh, Pa., December 5.

Charles Harland Downing, M.D., to Miss Lillian E. Marryatt, both of Everett, Mass., December 10.

Roscoe Earl Hamlin, M.D., Santa Rosa, Cal., to Miss A. Carmen Mouritz of Oakland, Cal., December 9.

Harvard Hersey Crabtree, M.D., Bangor, Maine, to Miss Constance M. Newell of Boston, December 2.

William Henry Haines, M.D., Pittsburgh, to Miss Mabel Estelle Bemis of Warren, Pa., December 9.

Arthur Columbia Pearman, M.D., to Miss Katherine Keeler, both of Rockford, Ill., December 12.

John Lyman Beard, M.D., Hillsboro, Cal., to Miss Clarice Pierson of Martinez, Cal., December 25.

Charles Robert Austrian, M.D., to Miss Florence Hochschild, both of Baltimore, December 9.

Le Roi Goddard Crandon, M.D., Boston, to Mrs. Lucy E. Gill, in New York City, December 15.

Walter Edgar Barbour, M.D., Seville, Ga., to Miss Leake Clark of Atlanta, Ga., December 15.

Cuvier L. Clover, M.D., to Miss Freda Trainer Moore, both of Knox, Pa., December 21.

Solomon A. Weiss, M.D., to Miss Gertrude Marblestone, both of Chicago, December 6.

J. H. McKinney, M.D., Fulton, Ark., to Miss Cora Holthoff of Dumas, Ark., recently.

Deaths

Albert Freeman Africanus King, M.D. George Washington University, Washington. D. C., 1861; University of Pennsylvania, Philadelphia, 1865; a Fellow of the American Medical Association; professor of obstetrics and diseases of women and children in his Alma Mater, from 1871 to 1913, and dean of the institution from 1879 to 1894; professor of obstetrics in the University of Vermont, Burlington, from 1871 to 1913; president of the Washington Obstetrical and Gynecological Society, from 1885 to 1887, and of the Medical Society of the District of Columbia in 1883-84; acting assistant surgeon, U. S. Army in 1864; author of a manual of obstetrics; died at his home in Washington, December 13, from senile debility, aged 73. In tribute to Dr. King's memory the George Washington Medical School was closed on the day of his funeral.

Benjamin W. Smock, M.D. Hospital College of Medicine, Louisville, 1889; a Fellow of the American Medical Association; for twenty years health officer of Jefferson County, Ky.; sanitary inspector of the State Board of Health and a commissioner of the Lakeland State Hospital; aged 54, who had been in ill health for a long time; died at his home in Louisville, December 16, from the effects of an incised wound of the throat, self-inflicted, it is believed, with suicidal intent, while of unsound mind.

James Delaforet Whitley, M.D. Rush Medical College, 1874; a member of the Illinois State Medical Society and a Fellow of the Royal Microscopical Society of London; a veteran of the Civil War in which he served in the Hospital Corps; local surgeon of the Chicago and Alton Railroad; medical health officer of Petersburg, Ill., for sixteen years; died at his home in that city, December 12, aged 70.

Louis Kolipinski, M.D. Georgetown University, Washington, D. C., 1883; a Fellow of the American Medical Association and a well-known practitioner and pharmacist of Washington; resident physician to the Children's Hospital and professor of surgery in the National University Medical College; died in a street car in Washington, December 15, from cerebral hemorrhage, aged 55.

Frank McWilliams, M.D. University of Pennsylvania, Philadelphia, 1899; a member of the Medical Association of the State of Pennsylvania and of the National Association for the Study and Prevention of Tuberculosis; for many years a member of the staff of St. Joseph's Hospital, Reading, Pa.; died at his home in Schuylkill Haven, Pa., December 16, from pneumonia, aged 40.

Winfield Scott Smith, M.D. Boston University School of Medicine, 1883; professor of operative surgery in his Alma Mater; and surgeon to the Massachusetts Homeopathic and Symmes hospitals, Boston, Arlington City Hospital, Quincy Hospital and Leonard Morse Hospital, Natick, Mass.; died at his home in Brookline, Mass., December 16, aged 53.

William H. Carter, M.D. Barnes Medical College, St. Louis, 1896; of Poolville, Tex.; formerly secretary of the Medical Board of Examiners for the forty-eighth Texas district; physician of Tarrant County, Tex., and a member of the staff of the Tarrant County Hospital; was shot and killed in Poolville, December 15.

Charles William Trueheart, M.D. Medical College of Virginia, Richmond, 1864; who was made an honorary member of the Bexar County (Texas) Medical Society in 1914; a Confederate veteran; for many years city health officer of Galveston, Texas; died at his home in San Antonio, Texas, December 14, aged 77.

Frederick Lewis Foster, M.D. Hahnemann Medical College, Chicago, 1900; a Fellow of the American Medical Association; city physician of Fond du Lac in 1903; a specialist on diseases of the eye, ear, nose and throat; died at his home in Fond du Lac, December 10, from pneumonia, aged 41.

Alexander J. Mitchell (license, Kentucky, 1881). For forty-three years a practitioner of Wirt County, W. Va.; and for several terms a member of the legislature; a member of the state mine commission; died at his home in Burning Springs, W. Va., December 9, from heart disease, aged 69.

Robert S. Talbot, M.D. Medical College of Virginia, Richmond, 1902; formerly of Lynchburg and Richmond, Va.; a member of the staff of the Central State Hospital, Petersburg, from 1903 to 1906; died at the Retreat for the Sick in Richmond, December 10, aged 37.

James S. McCorkle, M.D. University of Nashville, Tenn., 1860; a surgeon in the Confederate army during the Civil War and for more than thirty years a practitioner of Arkansas; died at his home in Fort Smith, December 11, from disease of the bladder, aged 79.

Ella Averill Patterson, M.D. Woman's Medical College of Pennsylvania, Philadelphia, 1901; who did heroic service at her home city, Butler, Pa., during the recent epidemic of typhoid fever; died at the home of her mother in Philadelphia, December 17, aged 36.

William H. Turkopp, M.D. Starling Medical College, Columbus, Ohio, 1879; for twenty-five years a practitioner of Yankton, S. Dak., but for the last ten years a resident of Columbus, Ohio; died at his home in that city, December 9, from nephritis, aged 59.

Frank Leslie Stallings, M.D. Kentucky School of Medicine, Louisville, 1901; a Fellow of the American Medical Association; died at his home in Lindsey, Cal., December 12, from septicemia, two days after an operation for abscess of the arm, aged 53.

Addison H. Bowser, M.D. Western Reserve University, Cleveland, 1885; a member of the Medical Society of the State of Pennsylvania and formerly a practitioner of Reynoldsville; died in the Warren (Pa.) State Hospital, December 8, aged 52.

John Wiebly Bealor, M.D. Washington University School of Medicine, Baltimore, 1876; a member of the Medical Society of the State of Pennsylvania; died at his home in Shamokin, December 11, from cerebral hemorrhage, aged 60.

William Higginbotham, M.D. Queen's University, Kingston, Ont., 1871; for many years a practitioner of Omemee, Brantford and Walker, Ont.; died at the home of his daughter in Brantford, December 15, aged 66.

John A. Dix, M.D. Eclectic Medical Institute, Cincinnati, 1871; a pioneer practitioner of Whitman County, Wash., and a veteran of the Civil War; died at his home in Garfield, Wash., December 9.

permitted; but to an intelligent and earnest judge it soon became apparent that the services of a man skilled in the examination of juvenile offenders was of great assistance to him in the adjudication of the cases. Finally, this assistance has become so valuable as to be indispensable. Judge Pinckney, the exceptionally able incumbent of the bench at the Juvenile Court, has averred that he could not go on with his present work without the help of Dr. Healy, who has been the institute's director since the beginning, or some equally efficient aid. So evident has the value of this work become to judiciary, police, attorneys, probation officers, criminologists and sociologists, that emissaries from many cities in this country and Europe have come to observe and have gone home to institute similar bureaus. Seattle was the first to follow us, Boston next, Munich soon after, and now the Municipal Court of Chicago has its own expert.

For five years Mrs. W. F. Dummer and her sisters supported the institute as a private benefaction with public functions, but now Cook County has awakened to its duty and opportunity, and has taken over the institute as an official adjunct of the Juvenile Court. Medical men everywhere should know of and appreciate the importance of this innovation, because,

Fourth, when the opportunity arises for them to assist in the installation of similar officers in their own cities and towns, it is to be hoped that they will earnestly further this step forward in scientific research, common humanity and the administration of justice.

Hugh T. Patrick, M.D., Chicago.

Postgraduate Study: Facilities in New York

To the Editor:—I did not realize how far Boston is from New York until I read in The Journal, Dec. 12, 1914, p. 2150, the communication on postgraduate study by Dr. Hugh Payne Greeley of that intellectual center, which is concluded thus: "Let us at once set to work and organize ourselves for this task and give to American physicians practical postgraduate work in *our own* language, and with our own *trade-mark*."

For nearly thirty-three years, there have been actively and successfully engaged in "practical postgraduate work" and in "our own language" and with a distinctly American "trademark," two organizations of well-known medical teachers who have had in attendance on their demonstrations and at their lectures some 50,000 practicing physicians from our own continent and from all over the world.

The New York Polyclinic Medical School and Hospital and the New York Post-Graduate Medical School and Hospital have expended in buildings and equipment approximately $3,000,000, and nowhere in the world can be found better opportunities for a practical postgraduate training and "brushing up" than are afforded by these schools. Over 300 physicians and surgeons are devoting their time to this work, without one dollar of remuneration, and many of these have, in addition, given largely of their means to make postgraduate teaching in America the great success it has proved to be.

May I cite our Bay State brother to an extract from the Boston *Transcript* of Nov. 17, 1914, a paper which may be profitably read by every good American?

> "Nor can there be any question that the establishment of the Polyclinic (1881) was the chief stimulus to the advance of medical thought and science in the United States; a stimulus that was felt, not only throughout this country, in all of whose important cities one or more postgraduate medical schools have been founded, but across the sea as well, where the system has been adopted in London and other cities!"

No matter how "tremendous" may be "the impetus to postgraduate instruction on account of the European War," the two great schools of the metropolis are ready for the hoped-for influx and will meet every requirement.

John A. Wyeth, M.D., New York.

Provision for Infants in Chicago Municipal Tuberculosis Sanitarium

To the Editor:—In connection with the article of Dr. Alfred F. Hess of New York on "The Neglect to Provide for the Infant in the Antituberculosis Program" (The Journal, Dec. 19, 1914, p. 2176), I wish to state that the Chicago Municipal Tuberculosis Sanitarium, which is to open its doors about March 1, contains a provision for the new-born infants of tuberculous mothers. A description of this provision was given by Dr. Charles S. Bacon of this city, in his article published in The Journal, Sept. 6, 1913, p. 750.

The Chicago Municipal Tuberculosis Sanitarium which, with its ultimate capacity of 950 beds, is the largest municipal sanitarium in the country, has a comprehensive provision for children (240 beds for ambulant cases and a special provision for bed cases in the infirmary).

In addition to this the sanitarium has a nursery to which two classes of new-born infants will be admitted: (1) the new-born infants of tuberculous mothers confined in the maternity department of the sanitarium, and (2) the newborn infants of tuberculous mothers remaining at home, who are unable to arrange for safe and proper care of the infant at home.

This is the first arrangement of its kind in the country, and it will no doubt prove of great value in meeting one of the great needs of the tuberculosis situation in a large community. The initial provision in the Chicago Municipal Tuberculosis Sanitarium is for twenty infants, but this will be gradually extended to meet the needs of the situation.

I was very glad to learn from the article of Dr. Hess that this important phase of the tuberculosis situation is in a way to receive due recognition in New York.

Theodore B. Sachs, M.D., President.
Chicago Municipal Tuberculosis Sanitarium.

Queries and Minor Notes

Anonymous Communications and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

DENATURED ALCOHOL

To the Editor:—1. By what process is alcohol denatured? 2. Can it safely be used for bathing purposes?

J. G. Pettit, M.D., Weston, W. Va.

Answer.—1. Alcohol ordinarily is denatured according to the following formula: "To 100 parts by volume of 90 per cent. alcohol add 10 parts of approved wood alcohol and one-half of 1 part of approved benzin." In other cases the use of 2 parts of approved alcohol and one-half part of approved pyridin is permitted. Information on this question can be obtained by addressing the Treasury Department, Bureau of Internal Revenue, Washington, D. C.

2. The external use of any alcohol containing wood spirits is unsafe.

REMOVAL OF RUST FROM INSTRUMENTS

To the Editor:—Can you give me a formula for removing rust from instruments?

James M. Adams, M.D., Amite, La.

Answer.—Instruments can be prevented from rusting in the process of sterilization by adding some sodium bicarbonate to the water in which they are boiled. A good polishing powder may be of aid in removing rust already formed.

LITERATURE ON FUNCTIONAL TESTS OF THE LIVER AND PANCREAS

To the Editor:—I should like to be informed as to the nature and methods of some of the newer tests of the functioning power of the liver and pancreas. These new tests do not seem to be mentioned in any of the newer works on diagnostic tests which I know of. Any information concerning them, or any literature which describes them, will be exceedingly opportune.

87. Splenomegaly in Children.—Nobel and Steinebach describe a case of successful splenectomy for cirrhosis of the liver in a child of 8. The icterus disappeared eight days after the operation and the enlarged liver decreased markedly in size. The case could not be followed any further. Eppinger has recently collected the cases in which splenectomy has been performed for hypertrophic cirrhosis of the liver, and the results show that the operation is justified. A histologic picture of the spleen in some cases is given, showing a marked increase in connective tissue. The changes are similar to those in Banti's disease, and the similar results of splenectomy also indicate a relationship. But there are many points of difference in their symptomatology and course, although it seems certain that the spleen plays a part in the pathogenesis of both.

They further describe two cases in which splenectomy was performed for acquired hemolytic icterus. The icterus and anemia disappeared soon after the operation and did not return and the reds became normally resistant. Banti performed splenectomy in hemolytic icterus and obtained recovery; since then it has been performed with success by numerous surgeons. It is most successful in the familial form, but Mitchell has reported good results in acquired hemolytic icterus. The brilliant results of splenectomy have caused many to believe that the spleen plays the chief part in the pathogenesis of hemolytic icterus. But the early improvement does not always persist, so that there must be a primary change in the red cells or defective functioning of the bone marrow. Eppinger holds that a supernumerary spleen or hemolymph glands may enlarge and assume the pathologic function of the spleen. Sometimes adhesions are formed after the operation that result in serious consequences for the patient. In the second case described they finally caused death. This must be taken into consideration in deciding the indications for the operation.

89. Alimentary Fever.—Lövegren has performed a series of experiments on dogs in an attempt to settle some of the disputed points in regard to alimentary fever, foremost among which is the question of whether the fever is really caused by the food or by bacterial invasion. He injected solutions of various kinds, salt, sugar and Ringer's solution, directly into a mesenteric vein, so that they reached the portal circulation directly, during the process of digestion. He gives the reports of the individual experiments and forty-one fever curves in the text. There is also a bibliography of [illegible] titles.

He found that fever really is caused by certain constituents of the food, chief among them salt and sugar. The effect is greater when the solutions are introduced directly into the portal circulation than when the injections are made into the peripheral veins. There is probably a biochemic-physical effect on the liver cells, the nature of which, however, is not definitely known. The fever is less with an isotonic solution than with either the hypertonic or hypotonic, and it is higher with milk sugar than with grape sugar. The leukocyte counts in his animal experiments were similar to those found by Rosenstern in clinical cases.

96 *Echinococcus Disease of the Lungs and Pleura. G. Cerulli.

94. Iodoform in Pneumonia.—Cardilli reports eight cases of secondary pneumonia and five of primary in all of which he gave intravenous injections of a suspension of 1 gm. of iodoform in 20 gm. of a concentrated solution of glucose. There was unmistakable benefit in the secondary cases but not in the primary ones; the injections in this case generally came too late. The usual dose was 15 c.c. of the suspension daily or on alternate days in the seven cases in which the pneumonia was secondary to typhoid, and all these patients promptly recovered. From seven to eleven injections were made in the various cases. The patients bore the injections well; there was no cyanosis or pallor, but merely slight and transient increase of the dyspnea and rise in temperature after the first injection. In some other cases the postoperative pneumonia showed great benefit from the injections; one instance is related in detail. In a number of the above cases Cardilli had considered the patients beyond hope, but the injections tided them past the danger point. The experience with the cases of primary pneumonia was not encouraging. There is no need for the injections in mild cases, and in the severe the drug has no chance for effectual action. He always gave thymol by the mouth and digitalis as need, supplementary to the injections of iodoform.

96. Echinococcus Disease of Lungs and Pleura.—In Cerulli's two cases the cough and pain in breathing simulated a tuberculous process in the lung, but there was no blood in the sputum and percussion showed an area of dulness with convex or concave upper margin, and when the patient was sitting up the dulness extended higher in front than at the back, thus excluding an ordinary pleural effusion. The parasites were all dead in the focus on account of the suppuration, and probably for this reason there was no eosinophilia. In his experiences otherwise he found it marked in about two-thirds of the cases. His successful operative treatment confirms the value of prompt operative measures on even the suspicion of echinococcus disease in the lungs and pleura. Under expectant treatment there is danger of suppuration, absorption of toxins from spontaneous [illegible] perforation and vomica, and an emergency operation may come too late.

Provision for Infants in Chicago Municipal Tuberculosis Sanitarium

To the Editor:—In connection with the article of Dr. Alfred F. Hess of New York on "The Neglect to Provide for the Infant in the Antituberculosis Program" (The Journal, Dec. 19, 1914, p. 2176), I wish to state that the Chicago Municipal Tuberculosis Sanitarium, which is to open its doors about March 1, contains a provision for the new-born infants of tuberculous mothers. A description of this provision was given by Dr. Charles S. Bacon of this city, in his article published in The Journal, Sept. 6, 1913, p. 750.

The Chicago Municipal Tuberculosis Sanitarium which, with its ultimate capacity of 950 beds, is the largest municipal sanitarium in the country, has a comprehensive provision for children (240 beds for ambulant cases and a special provision for bed cases in the infirmary).

In addition to this the sanitarium has a nursery to which two classes of new-born infants will be admitted: (1) the new-born infants of tuberculous mothers confined in the maternity department of the sanitarium, and (2) the new-born infants of tuberculous mothers remaining at home, who are unable to arrange for safe and proper care of the infant at home.

This is the first arrangement of its kind in the country, and it will no doubt prove of great value in meeting one of the great needs of the tuberculosis situation in a large community. The initial provision in the Chicago Municipal Tuberculosis Sanitarium is for twenty infants, but this will be gradually extended to meet the needs of the situation.

I was very glad to learn from the article of Dr. Hess that this important phase of the tuberculosis situation is in a way to receive due recognition in New York.

Theodore B. Sachs, M.D., President.
Chicago Municipal Tuberculosis Sanitarium.

Queries and Minor Notes

Anonymous Communications and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

DENATURED ALCOHOL

To the Editor:—1. By what process is alcohol denatured?
2. Can it safely be used for bathing purposes?

J. G. Pettit, M.D., Weston, W. Va.

Answer.—1. Alcohol ordinarily is denatured according to the following formula: "To 100 parts by volume of 90 per cent. alcohol add 10 parts of approved wood alcohol and one-half of 1 part of approved benzin." In other cases the use of 2 parts of approved alcohol and one-half part of approved pyridin is permitted. Information on this question can be obtained by addressing the Treasury Department, Bureau of Internal Revenue, Washington, D. C.

2. The external use of any alcohol containing wood spirits is unsafe.

REMOVAL OF RUST FROM INSTRUMENTS

To the Editor:—Can you give me a formula for removing rust from instruments? James M. Adams, M.D., Amite, La.

Answer.—Instruments can be prevented from rusting in the process of sterilization by adding some sodium bicarbonate to the water in which they are boiled. A good polishing powder may be of aid in removing rust already formed.

LITERATURE ON FUNCTIONAL TESTS OF THE LIVER AND PANCREAS

To the Editor:—I should like to be informed as to the nature and methods of some of the newer tests of the functioning power of the liver and pancreas. These new tests do not seem to be mentioned in any of the newer works on diagnostic tests which I know of. Any information concerning them, or any literature which describes them, will be exceedingly opportune.

R. J. Midgley, M.D., Salt Lake City.

ANSWER.—The following is a list of published articles on this subject:

LIVER

Schirokauer, H.: Alimentary Levulose Blood Test of Functioning of Liver, *Ztschr. f. klin. Med.*, 1913, lxxvii, Nos. 5 and 6; abst., THE JOURNAL, Jan. 3, 1914, p. 83.
Nesbitt, G. E.: Tests for Liver Function, *Dublin Jour. Med. Sc.*, November, 1913.

AUTO ANTIFREEZING SOLUTION

To the Editor:—I want to know the freezing point of denatured alcohol. The question arose while discussing its antifreezing power in comparison with wood alcohol in an automobile radiator. I have no chemistry on that point. B. J. BILL, M.D., Genoa Junction, Wis.

ANSWER.—We have no information on the freezing point of wood alcohol and water mixtures. Mixtures of denatured alcohol with water are used more frequently because of the lower cost of the denatured alcohol (55 cents per gallon, as against 75 cents per gallon for wood alcohol). A mixture of 1 part denatured alcohol and 3 parts water is said to withstand a temperature of 0 F. A mixture of 3½ parts of denatured alcohol and 6½ parts of water freezes at about 15 F. below zero, and a mixture of 4 parts of denatured alcohol and 6 parts of water freezes at about 25 F. below zero.

FINSEN RED LIGHT IN SMALL-POX

To the Editor:—In Abstract 77, THE JOURNAL, Nov. 28, 1914, p. 1939, is the statement that Würtzen insists that small-pox patients, sheltered against chemical light, as in a Finsen red-light room or in a dark room, do not suffer at all from suppuration and the variola changes its character completely.

It may be of interest to know that a distinguished English physician by the name of Gilbert, teaching at Montpellier at the end of the thirteenth century, insisted that his cases of variola be confined in rooms darkened by red curtains and red hangings, thereby lessening the severity of the disease; preventing suppuration and consequent disfiguration. If I am not mistaken Finsen received the Nobel prize in 1903 for rediscovering this fact.

HENRY F. ALBRECHT, M.D., Green Island, N. Y.

ANSWER.—The Nobel prize was awarded to Finsen for his work in phototherapy, particularly in lupus. The physician referred to is John of Gaddesden, court physician to Edward II. The treatment of small-pox by exclusion of light or by red light is said to have been employed since the time of John of Gaddesden by Picton, Black, Waters, Barlow and others. The red light treatment of Finsen has not been successful in the hands of Welch and Schamberg, Rickets and Byles, Brayton and others. See Schamberg, "Treatment of Small-Pox," in Musser and Kelly's "Modern Treatment," ii, 521.

MEDICAL STUDY FOR WOMEN IN VIENNA

To the Editor:—Please let me know whether women are admitted to medical study and examination in Vienna.

EMIL AMBERG, M.D., Detroit.

ANSWER.—In the chapter on "Medical Education of Women" in the Carnegie Foundation Report, Bulletin 6, 1912, p. 324, these statements are made:

"The most recent statistics for Austria show 80 registered women physicians, as compared with 9 in 1905, 34 in 1908; 39 of the 80 are settled in Vienna."

"Elsewhere, men and women attend the same classes and demonstrations, and, as at Vienna and Paris, dissect at the same tables. Coeducation is the general practice on the Continent."

Medical Education and State Boards of Registration

COMING EXAMINATIONS

ALABAMA: Montgomery, Jan. 5, 1915. Chairman, Dr. W. H. Sanders, Montgomery.

ALASKA: Juneau, Jan. 5, 1915. Sec., Dr. H. C. DeVighne, Juneau.

ARIZONA: Phoenix, Jan. 5-6, 1915. Sec., Dr. John Wix Thomas, 200 Nat'l Bank of Ariz. Bldg., Phoenix.

ILLINOIS: Chicago, Jan. 13-15, 1915. Sec., Dr. C. St. Clair Drake, Springfield.

INDIANA: Indianapolis, Jan. 12-14, 1915. Sec., Dr. W. T. Gott, State House, Indianapolis.

IOWA: Des Moines, Jan. 19-21. 1915. Sec., Dr. Guilford H. Sumner, Capitol Bldg., Des Moines.

MINNESOTA: Minneapolis, Jan. 5-8, 1915. Sec., Dr. Thomas McDavitt, 814 Lowry Bldg., St. Paul.

NEW MEXICO: Santa Fe, Jan. 11, 1915. Sec., Dr. W. E. Kaser, E. Las Vegas.

NEW YORK: Albany, Buffalo, New York, Syracuse, Jan. 26-29, 1915. Mr. H. H. Horner, Chief, Examination Division, State Education Bldg., Albany.

NORTH DAKOTA: Grand Forks, Jan. 5, 1915. Sec., Dr. G. M. Williamson, Grand Forks.

OKLAHOMA: Oklahoma City, Jan. 12-14, 1915. Sec., Dr. John W. Duke, Guthrie.

RHODE ISLAND: Providence, Jan. 7, 1915. Sec., Dr. Gardner T. Swarts, State House, Providence.

SOUTH DAKOTA: Pierre, Jan. 12, 1915. Sec. Dr. P. B. Jenkins, Waubay.

UTAH: Salt Lake City, Jan. 4-5, 1915. Sec., Dr. G. F. Harding, 407 Templeton Bldg., Salt Lake City.

VERMONT: Montpelier, Jan. 11-13, 1915. Sec., Dr. W. Scott Nay, Underhill.

WASHINGTON: Walla Walla, Jan. 5, 1915. Sec., Dr. C. N. Suttner, Baker Bldg., Walla Walla.

WISCONSIN: Madison, Jan. 12-14, 1915. Sec., Dr. John M. Beffel, 3200 Clybourn St., Milwaukee.

North Carolina June Report

Dr. Benjamin K. Hays, secretary of the North Carolina State Board of Medical Examiners, reports the written examination held at Raleigh, June 9, 1914. The total number of subjects examined in was 14; percentage required to pass, 80, and not less than 35 in any one branch. The total number of candidates examined was 118, of whom 81 passed and 37 failed. Twenty-six candidates were licensed through reciprocity. The following colleges were represented:

Book Notices

La Stase Intestinale Chronique. Par le Docteur E. Sorrel, ancien interne, lauréat des Hôpitaux de Paris. Paper. Price, 8 francs. Pp. 252, with illustrations. Paris: G. Steinheil, 1914.

The subject of chronic intestinal stasis has become quite popular of late, the term having been popularized by the writings of Lane. In this monograph the author reviews the subject historically, and then enters into an extensive description of the embryology, anatomy, histology and pathology of the large intestine. In discussing the theory of Metchnikoff that not only the appendix but also the cecum and colon are undergoing regression, and that they are not only useless but even harmful organs, the author says, "This appears to be going a little too far, but if it is difficult at least to admit that in a normal state the large intestine is a highly harmful organ it seems to be more admissible that in certain pathological states, particularly when there is a stagnation of the fecal matter, absorption of toxic products may take place from the large intestine and this is a point recognized by all to-day." Under pathogenesis of intestinal stasis the author considers the various theories which have been advanced, such as the cecum mobile of Wilms, typhlatonia of Fischler, habitual tortion of the cecum of Klose, Lane's kink, Jackson's membrane, chronic inflammatory adhesions, congenital folds, Hirschsprung's disease, etc. The author does not believe in Lane's mechanical theory as to the cause of the colonic adhesions, nor is he entirely convinced of the congenital origin of them. He says: "The matter is difficult to decide and it appears in practice one should not trust too much to the possibility of the congenital origin of the lesions, and to infer, therefore, that recurrence will not take place after section. It may be that there were primarily congenital lesions and no less true that at the time of intervention there may be other lesions added thereto, which one ought to take into account when it comes to the treatment." Under treatment the author quotes good results at the hands of and by the methods of each of the originators and defenders of the various theories mentioned. As some of the methods of treatment are the direct opposite of others, it is evident that the good results mentioned must often have been tempered with considerable enthusiasm. The author subdivides the various methods of treatment into three classes, namely, (1) the fixation of a part, (2) the liberation of adhesions of another part, and (3) the diversion of the intestinal contents by entero-anastomosis with or without exclusion, with or without resection. In the author's conclusions it is stated that the methods under the first class have been practically rejected. Those under the second find a more general application, while in the severer cases some of the methods under the third class will have to be resorted to. The volume closes with a report of several cases in which operation was performed according to the various methods by different operators, and a brief summary of the author's conclusions.

Tuberculosis of the Bones and Joints in Children. By John Fraser, M.D., F.R.C.S.E., Assistant Surgeon, Royal Hospital for Sick Children, Edinburgh. Cloth. Price, $4.50 net. Pp. 352, with 215 illustrations. New York: The Macmillan Company, 1914.

As an attempt to cover comprehensively this large and important subject, the book is not satisfactory. The sections on etiology and pathology are good, and form an epitome of the latest and best investigations. Proper emphasis is laid on the importance of recognizing tuberculous cow's milk as a dominant factor in the causation of the disease in children. The sections on diagnosis and treatment are disappointing. The descriptions of operations are often not sufficiently clear to be of use, and in some instances are distinctly incorrect, as in the cases of the Albee and the Hibbs operations on the spine. The photographs and photomicrographs are remarkably good and are valuable. Many of the line drawings, particularly of apparatus, are unworthy of a book of this character, and the crayon reproductions of Roentgen-ray negatives are wholly valueless.

Human Derelicts. Medico-Sociological Studies for Teachers of Religion and Social Workers. Edited by T. N. Kelynack, M.D. Cloth. Price, 5 shillings. Pp. 341. London: Charles H. Kelly, 1914.

This book is intended for the use of social workers, including clergymen, medical officers of health and teachers. The topics treated, each by a different author, include "Idiots and Imbeciles," "Lunatics," "The Feeble-Minded," "The Epileptic," "The Inebriate Derelict," "The Criminal Derelict," "The Recidivist," "The Mentally Defective Criminal Derelict," "The Vagrant," "The Prostitute," "Senile Derelicts," "The Derelict Deaf" and "The Derelict Blind." Naturally, a book which covers so wide a range of subjects within 350 pages cannot undertake an exhaustive discussion of any of them. The treatment, therefore, is that of the practical handbook: a general survey of each topic, a brief bibliography on each, references to recent legislation bearing on the class of derelicts under consideration, and the names and addresses of institutions and societies dealing with such derelicts. While of some interest to American readers, the book will find its greatest field of usefulness in Great Britain, since it is written from a British point of view and the practical information furnished bears chiefly on British institutions and legislation.

Practical Orthodontia. By Martin Dewey, D.D.S., M.D., Professor of Dental Anatomy and Orthodontia, Kansas City Dental College. Cloth. Price, $3.50. Pp. 342, with 248 illustrations. St. Louis: C. V. Mosby Company, 1914.

This book is an attempt to include certain principles which the author has found partially to fulfil the needs of his students. Like all other specialists, on the subject of orthodontia, the author is satisfied to base his premise on occlusion of the teeth, regardless of the etiologic factors giving cause and effect. While it is true that malocclusion will in a small measure influence the teeth in the wrong direction in their development, yet the great etiologic factors governing abnormal development are not appreciated or understood. Until dental specialists and teachers are able to grasp the broader principles of cause and effect, very little scientific progress can expected. Another criticism is the lack of giving due credit to those who have originated ideas and appliances and of which this work abounds. The mechanical appliances and their application are all that are to be desired for obtaining given results. The illustrations, paper and binding are good.

A System of Surgery. Edited by C. C. Choyce, B.Sc., M.D., F.R.C.S., Dean of Operative Surgery in the London School of Clinical Medicine. Pathological Editor, J. Martin Beattie, M.A., M.D., C.M., Professor of Bacteriology in the University of Liverpool. Volume III. Cloth. Price, $7. Pp. 901, with 276 illustrations. New York: Funk & Wagnalls Company, 1914.

This volume, edited by C. C. Choyce in collaboration with a number of notable English surgeons, is on a par with the two preceding volumes. The text is well written, the illustrations illuminating. The contributions are clear and concise, setting forth the essential features of the subjects under discussion. Perusal of the various chapters shows that the latest contributions to surgical knowledge have not been overlooked, while at the same time a certain conservatism is shown in avoiding the recommendation of methods of treatment which have not become recognized procedures by surgeons in general. As a student's text-book and as a work of reference this system of surgery cannot be too highly recommended.

Eye, Nose, Throat and Ear. A Manual for Students and Practitioners. By James Forrest, M.B., Ch.B., Resident Medical Officer Central London Ophthalmic Hospital. Cloth. Price, $4. Pp. 403, with 134 illustrations. St Louis: C. V. Mosby Company, 1914.

This volume is well illustrated and concisely written. Commoner ailments are described fairly completely while rare ones are only mentioned. Operative procedures are described in detail. The book is comprehensive for a manual, and contains a good index. An error, probably in proofreading, that may lead to confusion is found on page 358, where it is stated that esophagoscopy is performed in a similar manner to tracheotomy (tracheoscopy).

Miscellany

The New York Home Hospital—An Experiment

The New York Association for Improving the Condition of the Poor has for two years been carrying on an experiment of unusual interest. A report recently issued gives the experience of the association in conducting what is known as the Home Hospital Experiment, inaugurated two years ago for the purpose of answering, if possible, three questions: 1. Is it possible to treat families in which one or more members are afflicted with tuberculosis, keeping the family together in the home without danger to other members of the family? 2. Do the results of treating patients in their own homes under ordinary conditions of living with adequate medical supervision compare favorably with results secured by removing a patient from his home and treating him in a sanatorium or other institution for tuberculosis? 3. In the case of a family in which there is combined tuberculosis and poverty, which costs more, to treat the family as a unit, as is done at the Home Hospital Experiment, or to break up the home, as is done under other methods of treating families infected with tuberculosis? The limitations of the experiment required that a certain number of families afflicted with tuberculosis should be treated under conditions which would maintain the family life intact and independent, yet subject to the necessary conditions for recovery, and which would restore the family to its position as a self-supporting, wage-earning social unit. As the report truly says: "Tuberculosis is not merely a human disease; it is a social disorder, and the real problem is not alone the patients, but the family and the conditions under which they live." The Home Hospital, the first section of which was opened March 18, 1912, and the second Nov. 24, 1913, consists of forty-eight apartments of from two to four rooms, each including one or more bedchambers with open-air sleeping balconies. No expense was spared to provide these apartments with a maximum amount of sunlight and outdoor air. A solarium, a playground and a fresh-air school were established on the roof of the building. Four of the apartments were used for administrative purposes. In the remaining forty-four apartments selected families were installed, preference being given to families in which both poverty and tuberculosis were relatively incipient, to families possessing sufficient intelligence to cooperate, to families in which dependence was due to tuberculosis infection on the part of the wage-earner and to families in which tuberculosis of the mother rendered it impossible to keep the home intact under ordinary circumstances. This method provided for the oversight and care of children too young to be admitted to hospital sanatoriums, to patients unwilling or unable to leave their families and to the more or less chronic second stage, able-to-be-about cases, which are almost entirely unprovided for by other institutions. Careful investigation of family conditions was made in each case before admission and the plan was explained to each member of the family. All able-bodied persons were required to work and to account to the hospital for the expenditure of their incomes. Supervision and instruction by the resident staff and the attending physicians of the Home Hospital was insisted on. On the other hand, the association furnished to each family everything that was necessary for the maintenance of a normal standard of living and for the medical treatment of the patients in so far as the families themselves were not able to provide it. In a word, the experiment consisted of treating families for tuberculosis and the poverty which results therefrom, instead of treating individuals for tuberculosis alone. The social significance of this experiment can hardly be overestimated.

Space does not permit of a detailed résumé of the methods followed and the experiences acquired. Those interested in this unique experiment and its results will secure a copy of the report and study the details with care. The medical results for the first two years show that seventeen families have been rehabilitated physically and that eight others have been dismissed from the hospital either for frequent intoxication or for persistent refusal to follow advice and direction. The results obtained in the adult cases are 46.6 per cent. apparently cured, 35.5 per cent. arrested and 17.7 per cent. much improved. Every patient who has followed the advice given has improved, with the exception of one patient far advanced, who died 198 days after admission. No well member of any family has developed symptoms of the disease. Economically, the result is equally striking. Eleven families discharged as rehabilitated, had, on entering the hospital, an average. income of $6.34 a week. When discharged the average income of each of these families was $10.75 a week. Of the seventeen families discharged as rehabilitated during the two years of the experiment, the average income on admission was $6.37 a week; when discharged the average earnings were $12.41 a week. In other words, the family income had practically doubled in two years, while the condition of the infected members had greatly improved and the healthy members had been protected from infection. No more dependent invalids had been created, while the families had in each case been taught better, cleaner and healthier ways of living.

Financially, the experiment showed a balance sheet in its favor. Sixty-four families were admitted to the hospital during two years. The average number of individuals per family was five during the first year and 5.09 during the second year. Total days' care for patients and non-patients was 31,505 during the first year and 48,775 during the second year. The per diem cost per family during the first year was $3.54, during the second year, $3.32. The per capita per diem cost of both patients and non-patients was 70.8 cents the first year and 65.03 cents during the second year. Exclusive of administration, the per capita per diem cost was 50 cents and during the second year 47 cents. The total cost of the care of the sixty-four families during two years was $61,932.96, of which living expenses cost $38,000, administration and supervision $15,000, and general operating expenses made up the balance. The earnings of the families amounted to $15,313.06, making a total expenditure by the Home Hospital of $49,619.90. Doubling the capacity at the end of the first year reduced the cost of supervision and administration both per family and per capita.

An itemized statement of the various expenses is worthy of careful study, but cannot be quoted in detail. The essential factor in the entire plan, however, is the comparative cost of the Home Hospital and of the ordinary institutional method of treatment. In determining the average cost of institutional treatment, data from a large number of sources are assembled and analyzed, with the result that the average cost of maintenance of an advanced tuberculosis patient in an institute is estimated at $1.40 a day or $9.80 a week. The average cost of institutional maintenance for children and infants is standardized in the same way. Careful comparison is instituted in the case of different types of families; that is, those in which all members are infected, those in which all except the father and wage-earner are infected, etc. Comparison of the relative expense, in the case of a family in which the mother and one or more children have tuberculosis, and in which, under ordinary conditions, the family would be broken up and all except the father sent to public institutions, shows that under such a plan the net cost of maintenance, after the father's earnings are deducted, would be $23.75, which expense would fall on the public, while under the Home Hospital plan of keeping the family intact, the net cost after deducting the father's earnings is only $17.61, a saving of $6.14 a week, or $319.28 a year. The family is kept intact, the father and wage-earner is given a home, and the evils resulting from disruption of the family and institutional life are avoided. The actual cost of caring for tuberculosis families of all classes in the Home Hospital was found to be less than the cost of caring for the same family in institutions, while the social advantages gained by avoiding breaking up the family, depriving the well members of a home, subjecting the infected members to institutional conditions and increasing rather than correcting the dependency of the family, clearly shows the superiority of the home method over the ordinary institutional plan.

The experiment is one of the greatest importance and interest. Whether such methods can be applied to large numbers of families rather than to a few carefully selected ones, remains to be shown, but the experiment is a demonstration of the possibility of developing rational methods which will not disturb normal social and domestic conditions, and which will at the same time relieve the individual of the disease and the family of the social and economic consequences.

Medicolegal

Prosecution Under Wrong Provision and Indictment Erroneously Changed

(Rutherford vs. State (Tex.), 169 S. W. R. 1157)

The Court of Criminal Appeals of Texas reverses a conviction of pursuing the occupation of itinerant physician, going from place to place, in the practice of that profession, without paying the tax levied by law. The court says that it does not think the evidence would sustain the conviction. The evidence conclusively showed that the accused had been a resident of the city of Vernon for more than a year at the date of the institution of these proceedings, and that he was guilty of violating that provision of the code prohibiting any one practicing medicine without having obtained a license from the medical board and registering same, and not the article preventing one from practicing medicine as an itinerant physician without having paid an occupation tax. Had he paid the occupation tax under the evidence in this case, he would not have been authorized to practice medicine, and, as the evidence clearly showed that his fixed residence since he had been in the state had been at Vernon, he would not be liable for the tax levied on traveling physicians. Furthermore, in that part of the indictment wherein it was intended to allege that he "followed the occupation of physician, traveling from place to place," etc., the word "physician" was written "physicial," an "l" being written where it should have been an "n." It was moved to quash the indictment because there was no such occupation taxed as a "physicial," but, instead, the trial court ordered the clerk to change the indictment so as to read "physician." This it had no authority to do, as this word was a matter of substance in the offense charged, and, under the code of criminal procedure, an indictment cannot be amended in matter of substance. An indictment thus altered will not support a conviction. But had the trial court not undertaken to change the wording of the indictment, the whole context might have been sufficient, notwithstanding this mistake in spelling the word "physician."

Admissibility in Evidence of Physician's Book of Visits and Proof of Accounts

(Bellows vs. Bender et al. (N. Y.), 149 N. Y. Supp. 548)

The Supreme Court of New York, Appellate Term, Second Department, reverses a judgment entered for the plaintiff, a physician, against the defendants, executors, for professional services rendered to their testator, a new trial being ordered because of error in the admission in evidence of the physician's book of visits and proof of claim. The court says that the plaintiff was permitted to testify that the book was one in which he kept the accounts of patients visiting him and whom he treated; that the entries were made by him on the respective dates shown by the entries; that the book showed an account with the decedent; that the page of his account book purporting to show his attendance in this case was an account which he made up and entered each time the patient came to his office. Besides proving by another physician, who claimed to have been present at the plaintiff's office on the occasion of some visits made by the patient to the plaintiff, and who gave no evidence regarding the book entries, there were called by the plaintiff two patients or persons by whom it was sought to prove that they had settled their accounts with the plaintiff by his books. Unless it was made clearly to appear that these two persons, or at least one of them, had settled his accounts with the plaintiff according to his books and on the strength thereof, the proof that the book was correct was made by the plaintiff alone. One of the witnesses testified that whenever the plaintiff rendered a bill he paid it, that he kept track of all his visits, "but no track of his books." The second witness, when shown what purported to be her account, said that she had never seen that account before, and, like the other witness, testified to nothing from which it could be found that she had settled her accounts with the plaintiff from his book. To make such witnesses competent, they must testify that they settled their accounts by the plaintiff's book, and not by bills rendered to them. In Swan vs. Warner, 197 N. Y. 190, which was an action brought to recover for professional services rendered as a physician, the court reiterated the much-cited rule governing the admission of a party's books "for the purpose of sustaining his claim in an action like this," that rule being: "They ought not to be admitted where there are several charges, unless a foundation is first laid for their admission, by proving that the party had no clerk, that some of the articles charged have been delivered, that the books produced are the account books of the party, and that he keeps fair and honest accounts, and this by those who have dealt and settled with him." If the foregoing analysis of the testimony was correct, there was nothing left in the case to prove that the plaintiff kept correct books of account, apart from his own testimony, and that was insufficient to authorize the reception of a book under the account book rule. In the case of a physician, the books should show visits to patients, regularly entered in the course of professional duties. Their total number furnishes a basis for proof by other physicians of value according to the accustomed charges in the locality, and when coupled with independent evidence that some of the visits were actually made, and that other patients had settled their accounts with the physician from his books, the entries of his visits or attendance on them therein stated being correct and true, a physician's book of visits is then open for the inspection of the court, and, if found free from suspicion and sufficiently orderly to convey intelligence on perusal, the book becomes competent evidence of the visits before the court or the jury, as the case may be. Nor could the value of the plaintiff's services be proved by an entry which he made of a bill sent to the estate.

Manslaughter in Death from Roentgen Rays—Culpable Negligence—Judicial Notice

(State vs. Lester (Minn.), 149 N. W. R. 297)

The Supreme Court of Minnesota affirms an order overruling a demurrer to an indictment charging the defendant with manslaughter in the second degree, under a statute declaring manslaughter to be of this degree when committed without any design to effect death, "by any act, procurement or culpable negligence" not constituting a higher crime. The indictment alleged, among other things, that the defendant, without authority of law, but without a design to effect her death, did feloniously use and employ on the body of a named patient a Roentgen-ray machine for the purpose of taking a roentgenogram of her hip for his own sole use and purpose, with her consent, extracted from her on his assurance that it would do her no harm; that the machine was dangerous, except when operated by a skilful manager, which the defendant knew, or, in the exercise of the care required under the circumstances, he should have known, and yet he placed the tube unreasonably close to her body, and, disregarding his duty to her, he negligently and carelessly failed to give her proper attention, operated the machine in an unskilful manner, and kept her body so exposed for an unreasonable length of time, thereby inflicting on her body, in the region of the right hip, a mortal burn, from which she died. The court thinks the indictment sufficient, although it was not a model one.

The important question was whether the criminality of the defendant's acts as constituting the crime of homicide by "culpable negligence" was sufficiently alleged. Not every careless or negligent act whereby death ensues comes within the statute, and something more must appear than the essentials necessary to impose civil liability for damages. When considered as the basis of a charge of manslaughter against a medical man, or person assuming to act as such, culpable negligence exists where he exhibits gross lack of competency or inattention, or wanton indifference to the patient's safety, which may arise from his gross ignorance of the science or through gross negligence in either its application or lack of proper skill in the use of instruments. Where, however, he does nothing that an ordinarily skilled and careful practitioner might not do, and death results merely from an error of judgment or accident, no criminal liability attaches. "Gross," as here used, is intended to convey the idea of recklessness with regard to the safety of others, or "foolhardy presumption."

The failure to allege knowledge on the defendant's part that his acts involved probability of serious consequences to the patient was not fatal to the indictment, the defect, if any, in this regard, being cured by the presumption of contemplation of probable consequences. Neither was it necessary to allege the defendant's duty to the patient under the circumstances, nor to set up a specific standard by which his acts might be measured, these being matters of law. If, then, the facts alleged showed such incompetency or inattention or indifference to the safety of the patient as has been indicated as necessary to give rise to criminal liability, the indictment must be upheld, though it charged neither "culpable" nor any other degree of negligence by name, nor the defendant's acts in other than general terms and as ultimate facts.

The court takes judicial notice that Roentgen-ray machines sometimes inflict serious burns, and the indictment characterized the instrument used as dangerous, unless skilfully handled, and presumptively known to the defendant to be such, notwithstanding which he placed it too close to his subject, and also failed during an excessive exposure to give the attention requisite to prevent injury. These allegations imported criminal negligence.

Society Proceedings

JOINT MEETING OF THE NEW YORK NEUROLOGICAL SOCIETY AND THE NEUROLOGICAL SECTION OF THE NEW YORK ACADEMY OF MEDICINE

Held Nov. 10, 1914

Dr. Smith Ely Jelliffe in the Chair

Scleroderma, with Contractions

Dr. S. P. Goodhart: An unmarried girl, aged 24, about nine years ago noticed a swelling of the toes, followed by increasing stiffness of the toes and knees, and a feeling of coldness and weakness in the lower extremities, with paroxysmal attacks of whiteness of the skin of the hands, together with pain and tingling. With the disappearance of the blanching, the hands would become congested and then cyanotic. The hands lost in function, and flexure contractures soon appeared. These symptoms for a time increased in severity and then remained stationary. About five and a half years ago, the patient noticed pigmentation of the chest and a peculiar stiffness of the face, so that she was scarcely able to open her mouth. Some months later there was some improvement in the power of moving the knees and toes. When the weather was cold she noticed a numbness of the nose and tongue, but not of the lips or ears. The legs could be separated for a distance of only about 6 inches at the knees, owing apparently to fixation at the hip joints. Over the feet there was a hide-bound condition, but less marked than in the hands, which presented the typical appearance of a pronounced sclerodactylia. The face was distinctly masked in character, with all lines obliterated: the palpebral fissures were wide, giving a strange expression to the eyes. The margins of the lips were very narrow, and the mouth was held stiffly and always partially open, giving rise to a mummified expression. The nose was narrow and angular. The ears, which were indurated, thin and blanched, were held rigidly down. The mucous membrane of the mouth was becoming involved, showing some induration to the touch. The scalp showed no abnormality. The mammae were fairly well developed. Trophic disturbances were well marked over the small joints of the fingers and toes. The skin showed glossiness as well as pigmentation. Many scars were present, due to previous ulcers of the fingers and toes. A few years ago there was a slight but manifest diminution to painful stimuli from the finger-tips up to the wrists: this was also true of the feet and ankles. At present, no sensory changes were found excepting that there was a lack of proper appreciation of hot and cold stimuli.

DISCUSSION

Dr. Walter Timme: This condition is one of generalized connective tissue hyperplasia; the scleroderma is only a single manifestation. This hyperplasia is secondary, as a rule, to a disturbance of the sympathetic and autonomic nerve supply. In most of these cases there is a history of an antecedent high grade sympathicotonia, and as this increases, tissue hyperplasia begins, sometimes in the muscles and joints, and occasionally in the thyroid, the hypophysis cerebri and blood vessels. It is an overactive sympathetic and an underactive autonomic system. In the end, it probably resolves itself into a question of disturbance of the internal secretions, and from a therapeutic point of view we have seen some benefit from the use of various internal secretions.

Pilous Cerebral Adiposity

Dr. Walter Max Kraus: The patient, man, aged 31, had been accustomed to drink from five to seven glasses of beer daily up to the onset of his present illness in 1910. He smoked moderately. He gave a history of measles, chickenpox, diphtheria and whooping-cough in childhood, and some form of arthritis from the age of 24 (1908) until one year ago. The soles of his feet were sore, and later the tissues about the knees became red, swollen, hot and painful. After several of these attacks, there was some limitation of motion, but one year ago, the patient was cured. Between the ages of 3 and 4 years he fell from the fifth story of his residence to the ground, resulting, as he states, in a fracture of the crown of the skull. He was unconscious for about fourteen hours and disabled for six months. From that time until the age of 13 he was entirely well. Then he began to have attacks of Jacksonian epilepsy, which occurred from three to six times yearly and were not of sufficient severity to cause the patient either to tell his parents or seek the aid of a physician. At the age of 25, a little over twelve years after the first attack, the attacks ceased and had not since recurred.

Four years ago, at the age of 27, the patient began to grow fatter. At that time his weight was 150 pounds; in 1912 it had increased to 204 pounds; in 1913 to 263 pounds, and his weight at the present time is 282 pounds. At about the same time as this increase in adipose tissue began, the following symptoms made their appearance: His hair began to increase over the trunk and extremities, he felt sleepy, and as time went on he would fall asleep involuntarily in addition to sleeping a good deal voluntarily. In 1910, while driving a large automobile truck, he fell asleep, allowing the truck to run into a building. These narcoleptic attacks have continued since. The patient's appetite for food, especially meat and carbohydrates, has increased. He also complains of shortness of breath and sweats a good deal. Three and a half years ago he noticed that the penis was smaller and that shortly afterward his sexual desire grew less until now he has none at all.

DISCUSSION

Dr. I. Abrahamson: In Mount Sinai Hospital there is now a young woman with very similar manifestations. She gives a history of amenorrhea, hyperhidrosis, peculiar skin changes and adiposity; she complains of sleepiness and has a growth of hair on the face and body, but the urine contains sugar and shows evidences of an advanced nephritis. A blood count gave 6,100,000 red cells and 10,000 white cells, with 110 per cent. of hemoglobin. The urine constantly contains a small percentage of sugar. The facies is like a typical one of polycythemia. The moist skin in this case might be attributed to the nephritis as well as the polycythemia, but is most likely a part of the polyglandular disease.

Dr. Walter Timme: The hypertrichosis present in this case is not quite as generally distributed as stated. On closer inspection it is seen that the distribution is radicular in character, and furthermore skips the areas supplied by the cervical roots, to begin again at the dorsal level. This arrangement corresponds with the position of the cells of the superior spinal sympathetic nucleus, which is non-existent in the cervical region of the cord, and begins at about the first dorsal level. This is rather suggestive, therefore, of sympathetic involvement.

AMERICAN ASSOCIATION FOR STUDY AND PREVENTION OF INFANT MORTALITY

Fifth Annual Meeting, held at Boston, Nov. 12-14, 1914

Under the presidency of Dr. J. Whitridge Williams, Baltimore

Prenatal Care

Dr. Arthur B. Emmons II, Boston: Prenatal care is preventive medicine as applied to obstetrics. To obtain the greatest efficiency there must be cooperation of the various scientific laboratories in the medical school to further our knowledge. The medical societies and journals should disseminate authoritative knowledge. The hospitals must also cooperate by providing ample care for doubtful and dangerous cases. The state and municipal health boards, milk stations and social forces, both public and private, should cooperate to make its application to the community possible, as well as the efforts of patient and family.

DISCUSSION

Mrs. Max West, Federal Children's Bureau, Washington, D. C.: Two of the most important pieces of prenatal work in this country are those undertaken in Boston in 1909 by the Women's Municipal League, and in New York in 1911 by the New York Milk Committee. The statistical results of these two experiments prove conclusively that prenatal care, systematically and intelligently given, lowers the number of stillbirths and miscarriages, decreases the number of babies who die under 1 month of age, and increases the number of breast-fed babies. In Boston the stillbirth rate was about 40 for every thousand living births; among supervised mothers it was about 28. In New York the rate was 47.5 for Manhattan at large, and 39.8 among supervised mothers. In Boston the average weight of the babies of supervised mothers was 7 pounds, 11 ounces, including prematures, an increase of several ounces over the usual average. The importance of prenatal care in establishing breast feeding is shown in every city where records have been kept. Prenatal work is now being done to a greater or less extent in about forty cities of this country, by fifty or more organizations, but is yet in its infancy.

Dr. S. Josephine Baker, New York: Among the mothers that have been under our care, approximately 500, we have had no deaths; 96 per cent. of the babies born are living now; the deaths under 1 month per thousand births have been reduced about one-half. We have used the infants' milk stations as centers; here the women are registered, and they are visited every ten days before confinement and every day for ten days after birth of the baby, when they are referred back to the milk station for observation.

Miss Fanne F. Clement, Superintendent, Red Cross Town and Country Service, Washington, D. C.: In small communities the visiting nurse has perhaps from one to six physicians under whose direction her actual nursing services are rendered. If there is but one, as not infrequently happens, it becomes absolutely necessary that she have his good will and cooperation; otherwise her work cannot succeed. This attitude on the part of the physician in the country is a much more important item than in the city, where the sphere of the public health nurse as it relates to the medical profession is much better understood; not only by doctors but by the laity in general, who lend her moral support. The absence of hospitals, dispensaries and other health agencies in country districts leaves the greater responsibility in the hands of physicians and visiting nurse agencies in these sections, on whom it devolves to create and extend a public sentiment favorable to health. Not only are physicians in rural communities often few, but in many instances their lack of proper professional equipment and their unconcern for up-to-date knowledge in preventive medicine create a difficult situation for the public health nurse who has had special training for her work. Regarding prenatal visiting particularly, this has been found to be the case. A rural nurse in Maine reports that she is not permitted by the local doctor to make prenatal visits except in special instances. In a Pennsylvania community of 8,000 foreign population, where the visiting nurse is employed by an industrial company, she has gradually come to know practically every family. It has been her special endeavor to become friends with the mothers, so that they would allow her to make prenatal visits and be induced to employ physicians when their babies were born. Because a few mothers, in the beginning, liked the way the nurse cared for their babies, and first of all because they liked the nurse, all the mothers now call her, which means that the opportunity for prenatal visiting is greatly increased, that a physician is in attendance during delivery and that the midwives are seeking new fields. The two or three physicians with whom she works turn over to her charge expectant mothers reporting to them, and she visits them weekly.

Care of Institutional Infants Outside of Institutions

Dr. J. H. Mason Knox, Jr., Baltimore: Out of 229 foundlings committed by the city to institutions in the last ten years, 204, or 88 per cent., died within a few weeks. Many of these children were diseased and weak, but the large majority were healthy new-born babies, whose lives were lost simply because their environment was not suited to their needs. The institutions to which they were committed were excellent of their kind, good milk, regular feeding and kindly nursing was furnished. The thing that was lacking, and which seems to be essential for baby life is individualizing, motherly care and quiet.

Mortality in So-Called Foundling Institutions

Dr. Philip Van Ingen, New York: From 1909 to 1913 inclusive, 28,210 children under 2 years of age were cared for in eleven institutions in New York state, and the death rate for babies under 2 years for the same period, based on the total number of children cared for, varied in the different institutions from 183 to 576 per thousand, with a general mortality rate for the eleven of 422.5 per cent. for the five years. During the years 1909 to 1912 inclusive, the death rate for children under 2, based on the estimated population for the state at that age, was 87.4, practically one-fifth of that in institutions. In one institution which has a large maternity service, there were only four deaths of babies during the first week of life among 298 born during the year, a death rate of 13.4 per thousand, or 3.9 per cent. of the total mortality under 1 year. In a very high class obstetric hospital, the death rate under 7 days was 25.4. For the Borough of Manhattan it was 23.7, or 17.8 per cent. of the total deaths under 1 year. The stillbirth rate was 32.5, while that for Manhattan Borough was 48.1. After the first two months, however, this favorable start was overcome and the general death rate under 1 year of age for this group of babies was 488 per thousand. Of 1,738 babies admitted at various ages under 1 year, 22.7 per cent. died before completing the first month of residence and 34.9 before completing the second month. Of all deaths, 44.3 per cent. occurred in less than one month after admission, and 68.7 per cent. in less than two months.

University Extension Work for the Prevention of Infant Mortality

Dr. Dorothy Reed-Mendenhall, Madison, Wis.: The fundamental reason for high infant mortality in the rural districts is neglect of the childbearing woman. In country districts in Wisconsin deaths from puerperal fever, birth injuries, malformations and prematurity are about one-third more common than in the cities, and we have had larger statistics of still-born children in the rural districts, caused by neglected pregnancy and labor; this is easily doubled in the country districts as compared with the cities. The community welfare work of the University of Wisconsin has been in existence a little over two years; therefore the results are too small to make very much of. I believe, however, that we are meeting a hitherto unmet need of the community, and for this reason our work is of fundamental interest. Briefly, these are the methods: An advance agent is sent ahead, and a moral or welfare survey of the community or small town, usually a town of from one thousand to five or six thousand, is made, and in that way the special needs of the community, whether hygienic, moral or social, are found out. Then the university sends out experts from the university extension staff to talk on topics that have been suggested, such as the care and physical conditions of infants; why women should so often miscarry; why the children are still-born; why there is so much suffering from injuries incidental to childbirth; why they had caked breasts, milk-leg and fevers after childbirth, and talks on the care of the mother before and after confinement, as well as the care of contagious diseases in the home.

The Relation of Gynecologic Surgery to Bad Obstetrics

Dr. Edward Reynolds, Boston: Obstetric mortality is now generally low, but much of a woman's subsequent health depends on the conduct of her confinement. Poor attendance is usually followed by some degree of chronic ill health, which is sometimes subsequently remedied by a well-attended confinement. The ill effects of bad obstetrics may be either directly constitutional or the result of local injuries or infections. Bad obstetrics contributes to gynecologic surgery, chiefly tears, tubes and misplacements. Much depends on adequate care during convalescence. Obstetric care is in general much better than formerly, but there is still much room for improvement.

The Need of Hospitals for Maternity Surgical Cases

Dr. Edward P. Davis, Philadelphia: The advantages of the modern hospital for cases of parturition requiring assistance cannot be denied. The risk of infection and hemorrhage are reduced to a minimum, suffering is prevented, the patient is put in condition to make a prompt and thorough recovery, and the lives and health of mother and child are conserved by all the methods of modern science. What is needed to give confinement cases adequate hospital care is an adaptation of accommodations to the means of the community. Hospital beds at a price of from five to seven dollars per week, in small wards, are usually within the reach of any man who has work. A certain number of absolutely free beds should be available for those who honestly cannot pay. These small wards should be thoroughly comfortable, the friends of the patient should have access to her at definite hours, and the patient and her husband should be made to feel that their effort to compensate the hospital are appreciated and respected. The greatest need in hospital accommodations for confinement at present is private rooms at from ten to fifteen dollars per week.

Teaching Obstetrics: Necessary Equipment

Dr. W. W. Chipman, Montreal: The imperative and the absolute need is for a larger and more adequate teaching service in our hospitals and dispensaries. Each and every hospital is so much the better in its adequate care of the sick by very reason of its teaching; it is thereby saved from

Chauvinism and decay. This provision of clinical service is both the duty and the privilege of the laity to bestow. Each and every lying-in hospital should, if possible, be affiliated with a teaching school. The hospital is, or should be, the student's workshop. He begins at the beginning, doing things, and it is only in, and by, such service that he gains in any sense professional wisdom. For obstetrics, all this means the lying-in hospital.

COLLEGE OF PHYSICIANS OF PHILADELPHIA

Meeting held Nov. 23, 1914

Dr. James E. Talley in the Chair

Cirrhosis of Liver and Peritoneal Tuberculosis

Drs. B. F. Stahl and Norman B. Gwyn: A woman, aged 58 years, complained of pain in the lower left axilla. For many years she had been a steady drinker. She had been feeling poorly for about five weeks and occasionally was feverish. There was complete absence of physical signs, except a few crepitations in the left axilla. No malarial parasites could be found; the Wassermann test was negative, the tuberculin test weakly positive; the sputum was repeatedly negative for tubercle bacilli. The patient ate and slept well. A gradual wasting without pronounced anemia took place. At the end of five weeks there was distinct yellowing of the conjunctivae and enlarged veins coursing up over the thorax and down to the groins. The patient failed rapidly. Three days later swelling of the abdomen began and pain in the right side of the abdomen became marked. Four days later signs of fluid in the abdomen were distinct. At no time in the last ten days of life did it seem likely that operative measures would avail. The necropsy showed atrophic cirrhosis of liver, the organ being deeply indented, suggesting a syphilitic process. There was a small area of tuberculosis in the left upper lobe anteriorly. The interior of the abdominal wall was studded with irregular, small nodules; the mesentery studded with irregular, small nodules with hemorrhagic tops. The serous coat of the intestines had lost its gloss and a fine fibrinous layer was over all. In a good light minute tubercle-like formations were evident in abundance. The lower 8 cm. of the cecum was an immense, ulcerating, thickened mass; there were other ulcerations in the intestines, evidently tuberculous. Sections showed that the condition was tuberculous. Tubercle bacilli were found in macerated tubercles from the peritoneum.

DISCUSSION

Dr. John K. Mitchell: I had under my care about four years ago a somewhat similar case, in which the fever lasted for six months. Every night, with one or two exceptions, the man had a temperature of from 102 to 103.5 F. Tests of urine, feces and blood were negative. There were numbers of crystals of uric acid in the sweat, the odor of which was so bad that the man was obliged to get up in the night and take a bath. I sent him to the country and had him sleep outdoors. After two or three weeks the temperature fell and the man recovered in six or seven months. He is now perfectly well and weighs 190 pounds. The diagnosis is still in abeyance.

Dr. Robert N. Willson: Last year I saw a little girl who had what seemed to be a low grade bronchopneumonia. For two or three days her temperature was normal. Following that she would have a rise of temperature and then a return to normal. Headache was the only other symptom. This lasted for four months. Tuberculin tests were always positive, but we could not put our finger on a focus. Finally the abdomen became greatly distended. We operated and found in the center of the abdomen a large caseous tuberculous mass. This was removed with a tremendous loss of blood and the child died that night. Up to the day previous to the operation there was no suggestion of an abdominal condition, except a little tenderness over the appendiceal area.

Dr. Joseph Sailer: The association of tuberculosis and cirrhosis of the liver is interesting. In my experience with cirrhosis of the liver not one patient out of twelve had tuberculosis. In a case of prolonged fever there was also failure to reach a definite diagnosis. All tests were negative. The patient neither wasted nor gained and had a temperature between 99 and 100 F., occasionally reaching 101. This was before the days of the Wassermann test. On the basis of the possibility of syphilis, antisyphilitic remedies were used, but without result. Another patient had a daily temperature of 100 F. During six months' observation nothing definite appeared. The woman gained about 7 pounds on a prolonged rest cure, but did not lose her fever. Prolapse of the uterus was the only definite gynecologic symptom. Dr. Clark operated and a fairly large solid ovarian tumor was removed. The patient's temperature became normal and she completely recovered her health.

Dr. William M. L. Coplin: One point not accentuated is that in post-mortems we see an unusual type of tuberculosis in which caseation or other form of necrosis is slight or absent. The masses on the peritoneum in this case were elevated with hemorrhagic summits, often appearing almost papillomatous; the sand-grain surface of miliary tuberculosis was absent. There were one or two ulcers in the intestine, typically tuberculous. In many of these irregular forms of tuberculosis it is possible that we may find a tubercle bacillus of an unusual type. There is a fibrosclerotic change in the nodules which is very conspicuous. The appearance is almost that of complete healing, with absence of caseation, bringing forward the suggestion urged by French writers that there is a fibrogenic toxin produced by the tubercle bacillus differing from caseogenous toxin so characteristic of tuberculosis.

Typhoid Complicated by Orchitis

Dr. S. H. Rosenthal: The patient, aged 18, passed through a mild attack of typhoid; the temperature became normal on the thirteenth day. Twelve days later the patient was seized with intense pain in the left lower portion of the abdomen The temperature rose to 101 F., pulse rate, 120; leukocyte count, 28,000. Distinct rigidity and tenderness were present in this area and the patient vomited twice. The following morning the pain shifted to the left testicle, the abdominal pain subsiding. The testicle and epididymis were found very much swollen and tender and the scrotum inflamed, with tenderness along the vas and enlargement of the left inguinal glands. The leukocyte count gradually fell to 9,000. Twenty days after the onset of this complication an incision was made in the left testicle and pus was found. Typhoid bacilli were obtained in pure culture and were agglutinated by the patient's serum and the serum from another known typhoid case. The patient is still in the ward, the wound draining. There is no history of venereal infection. Orchitis and epididymitis are comparatively rare complications of typhoid fever, the percentage being about 0.2. Only a few more than 100 cases have been reported. Some arise from thrombosis of the spermatic veins; in a few the typhoid bacilli gain access to the epididymis and testicle by way of the vas from the urine, but in the majority of cases the source of infection is in the blood. The complication occurs most frequently between the ages of 15 and 25, appearing late in the disease or in convalescence, lasting from twelve to eighteen days and terminating in resolution, although induration and atrophy of the testicle or suppuration may occur. In the presence of suppuration there is apt to be extensive sloughing, which practically destroys the entire testicle.

DISCUSSION

Dr. Alfred Stengel: I believe that the estimate given by the latest literature of 108 cases of this complication of typhoid fever is far below the actual number. This opinion is strengthened by the personal observation of about six cases in 350 cases of typhoid. This is a late complication, and the confusion between a gonorrheal process and one due to typhoid is, therefore, not so likely to occur as one might at first think.

Dr. Joseph Sailer: The interesting features in this case are the pain referred to the abdomen from the very beginning, and the marked leukocytosis. I have not seen a frank case of orchitis such as this is, and I have seen at least 350 cases of this complication.

The Abderhalden Test with Its Relation to Disease of the Liver

Dr. Joseph Sailer and Dr. T. G. Schnabel: We obtained the following results in 43 cases examined: Five cases of secondary malignant disease of the liver, all strongly positive; 2 cases of cholelithiasis, 1 strongly positive and 1 faintly positive; 1 case of cholecystitis with adhesions and jaundice, moderately positive; 5 cases of atrophic cirrhosis, all probably alcoholic, 2 moderately positive, 2 very strongly positive and 1 negative; 4 cases of passive congestion of the liver secondary to cardiorenal disease, all strongly positive; 2 cases of enlarged liver, positive; 1 case of suspected liver disease without definite symptoms, faintly positive; 3 cases of syphilitic cirrhosis with Wassermanns all positive; 1 of these positive after the injection of salvarsan; 2 cases of hypertrophic cirrhosis, both positive. One case of renal insufficiency one week after induced abortion gave a strong reaction with liver, strong reaction with thyroid and intensely strong reaction with placenta. Another case of supposed puerperal infection gave a strong reaction with placenta, but none with either liver or thyroid. In a case of suspected pregnancy, afterward proved not to be, there was no reaction with either tissue. In two cases of lobar pneumonia the serum of both showed dialyzable substances and gave a positive reaction with ninhydrin. In one case of myxedema a very faint reaction was obtained with liver substratum but no others. In one case of known pregnancy there was no reaction with liver tissue, faint reaction with thyroid, and strong reaction with placenta. In a case of malaria there was a strong reaction with liver tissue, with kidney tissue, and with thyroid tissue. In a case of multiple serositis there was a faint reaction with liver, thyroid and placenta. In a case of recurrent alopecia, which had been diagnosed by two other physicians as disturbance of the thyroid gland, there was no reaction with any substratum. On the whole, the results indicated that the reaction was positive in the majority of known cases of liver disease and occasionally positive in cases not known or supposed to be liver disease, and in which the complete demonstration of a normal liver naturally could not be made.

4. **Histology of Bone Graft.**—Experiments were conducted by Gallie with a view to determining the successive histologic changes which occur in bone transplants. In each case the periosteum was removed from the graft before it was inserted. In four experiments the grafts were autogenous and the specimens were recovered after the lapse of one, two, three and eight weeks, respectively. In one experiment the graft was autogenous, but boiled before insertion. In another experiment a piece of cat's bone and in still another experiment a piece of human bone was grafted into a dog. These experiments demonstrated that following the successful transplantation of such bone grafts the following changes occur: 1. Death of the graft. 2. Revascularization of the graft. 3. Concomitant absorption of the dead bone and production of new bone by the bone cells which invade the graft along the route of the new blood-vessels. The experiments showed no difference in the value of fresh or boiled bone as a transplant and no difference in the gross and histologic changes, incident on the introduction of autogenous and heterogenous bone grafts.

5. **Experimental Study of Osteogenesis.**—All four series of experiments performed by Mayer and Wehner—transplants of periosteum, subperiosteal resections, cap implantations and bone transplants—combined to emphasize the osteogenetic function of the specific osteoblastic cells of the periosteum and the inability of the adult bone-cell to form new osseous growth. Bone growth occurred in all the transplants of periosteum, and from the periosteum after subperiosteal resection; it was, however, absent in the cap experiments in which the ingrowth of periosteum had been excluded. In the bone transplants, the adult bone-cells of the graft gave no evidence of activity whereas the periosteum showed marked osteoblastic properties. Similar osteogenetic power was manifested by the transplanted endosteal cells lining the marrow cavity and the Haversian canals, provided their vitality was maintained by intimate union with the tissues of the environment.

Bone macroscopically bare of periosteum was successfully transplanted into the soft parts, not because the bone cells gave rise to new bone formation, nor because of a metaplasia of the surrounding connective tissue cells into osteoblasts, but because of adherent periosteal cells, and of living endosteal cells. The practical conclusions for the surgery of bone transplants the authors consider to be self-evident; bone should be transplanted with the periosteum; if feasible, it should be split lengthwise, so as to insure an intimate union of the endosteum with the surrounding tissues. Bone macroscopically bare of periosteum can, however, be transplanted with good hope of success if care be taken not to scrape away the adherent cells of the osteogenetic layer of the periosteum.

The authors hold that the classical conception of a complete necrosis of the bony portion of the transplant must be modified since, though the majority of the transplanted bone cells necrose, numerous cells can maintain their vitality until the graft has become vascularized. These cells, however, give no evidences of osteogenesis. The process by which the necrotic bone of the transplant is replaced by living bone consists not only in the usual sequence of lacunar absorption and subsequent bone apposition, but in a "creeping replacement." In this process the young bone cells before they have assumed the adult form and before the bone has become lamellar in structure, show evidences of direct cell division, and of power to absorb necrotic bone and form new bone. The living osseous tissue advances into the old by the intercellular deposit of bone, also probably by a direct advance of the young bone cells in the old lacuna.

6. **Ununited Fractures with Study of Bone Repair.**—During the last five years Hawley has observed fifty-three cases of ununited fracture in a total of 1,200 cases of fractures. As a result of this experience, the following conclusions are drawn. Accurate approximation or near approximation, offers the most effective prevention of imperfect union, by lessening the distance to be bridged by capillary growth and bone-cell invasion. Gross hemorrhage interferes with frac-

ture repair, and it is a question whether extensive extravasation is not an indication for evacuation. The periosteum acts to protect the intrinsic process of repair from connective tissue intrusion from without. It also plays a small part, although not always a necessary part, in repair, by reason of its blood supply to the cortex and the bone cells nested around these periosteal capillaries. The promotion of bone regeneration by increasing the amount of calcium in the diet Hawley regards as of doubtful value. During fracture repair the normal demand for calcium is reduced; the only increase is limited to the site of fracture. Whatever influence the organs of internal secretion may have on bone nutrition, the nature of the control is unknown, and there is no evidence that gland feeding favors or retards callus formation.

Hawley urges that simple methods of treating delayed union should precede operative intervention, unless obvious reasons exist for early operation. Bone transplantation is the operation of choice, because buried metal frequently retards the healing process. It is doubtful if the freshening of the fracture surfaces has much merit in itself, for the secondary repair is less likely to be as vigorous as the first. So-called fibrous union may be due to defective vascular communication between fragments, or faulty function of the calcium depositing cells. In Hawley's opinion it is more often the latter. Massage, as it is commonly understood and practiced, Hawley says, should never be used in the treatment of ununited fractures.

12. **New Physical Sign in Lumbar Lesions.**—In various lesions of the lumbar spine, inflammatory and traumatic, Ely found that if the patient be laid on his face, when his knee is flexed his pelvis on that side will rise from the table. The exact reason for this phenomenon is not given, but it helps to differentiate lumbar from sacroiliac lesions, having possibly in the former the same value as Kernig's sign has in the latter.

32. **Use of Casein Calcium Milk in Treatment of Summer Diarrhea.**—During the summer of 1914 Rost used this milk in the treatment of fifty-six cases of summer diarrhea, no patient being ill less than three days. Age varied from 3½ months to 2½ years. Many of the children were rachitic, anemic, poorly nourished, underdeveloped and underweight. The original formula was adhered to, as a rule; dextri-maltose was rarely added before the third day; in about 50 per cent. of the cases, cereal decoction was employed instead of water; small amounts were given at four-hour intervals; water *ad libitum* if necessary; the total quantity of food was increased from 2 to 4 ounces daily, depending on the condition and age of the child. It was well taken by all except one. This milk was given for periods of time varying from four days to several weeks. No vomiting occurred. All cases showed improvement in about four days, the stool in most children assuming a yellowish color, semisolid, one or two movements daily. About 40 per cent. gained in weight and 21 per cent. remained stationary; in 30 per cent., the weight could not be observed on account of the very irregular attendance of the mothers.

Rost is convinced that casein calcium milk employed in dyspepsia (summer diarrhea) is productive of results rarely attained with the older methods of treatment. On account of the simplicity of its preparation and inexpensiveness, it is particularly useful in the management of nutritional disturbances applying to the outpatient departments for treatment. It may readily be used in those nutritional disturbances in which Finkelstein and Meyer's protein milk is indicated, but cannot be employed on account of its expense or taste.

36. **Epidemic of Small-Pox.**—The epidemic Young reports was one of the hemorrhagic and purpuric type which existed in Elm Springs Township, Washington County, Ark., during January and February, 1914. The interesting points in this epidemic are its high percentage of mortality, 90 per cent. of all unvaccinated adults, the recovery of all children afflicted, and the very evident effect that age had on the prognosis of the disease. The younger the child, invariably, the milder the attack. A successful recent vaccination in all cases was an absolute protection. Another point of interest in this epidemic lies in the fact that it came from old Mexico.

46. Abstracted in The Journal, July 18, 1914, p. 269.

47. **Variations in Sensory Threshold for Faradic Stimulation.**—The new Martin test (1908 et seq.) for variations in the sensory threshold for faradic stimulation has been used by Grabfield in an orientation study on 135 psychopathic subjects, ranging from the psychoneuroses to cases of coarse brain disorder. Repeated observations have been made in many cases. He found that the faradic threshold in psychopathic subjects of almost all kinds tends to be high, and in fact averages 223 beta units, as against 140. considered to be the highest range of normal subjects under ordinary circumstances, and 175, considered to be definitely pathologic. The average threshold for alcoholic cases was 252, and among alcoholic cases the polyneuritic or Korsakoff cases ran highest. On withdrawal of alcohol and in convalescence the threshold falls, and the method may even have practical value in gauging the degree of progress toward recovery in the delirium tremens group. The paranoidal forms of dementia praecox have a normal threshold, whereas those classed as catatonic and hebephrenic have pathologically high thresholds. The hebephrenic cases tested (two in number) showed some of the highest thresholds calculable (760). Eight catatonic cases averaged 232 (paranoid 131). The manic phase of manic depressive insanity shows a normal threshold, the depressive phase a pathologically high threshold. The psychoneurotics seem to have normal thresholds—hence there may be an immediate practical value diagnostically, when the diagnosis is in doubt as against the frank psychoses.

48. **Experience with Lange Colloidal Gold Test in Cerebrospinal Fluids.**—Solomon and Koefod tested 135 cerebrospinal fluids. The cases of general paralysis give fairly constant and characteristic reactions. The characteristic paretic reaction was typically given in 20 out of 25 cases. As they were not certain in many of the cases whether the diagnosis was paresis or cerebrospinal syphilis, the authors are unable to draw any conclusions from these tests as to the value of the method in differentiating the two. Of twelve cases of congenital syphilis, only one gave a marked reaction and that a case of juvenile paresis. There were 33 cases giving positive Wassermann reactions which were diagnosed as other than syphilis of the central nervous system. Of these, 10, or 30.3 per cent., gave some reaction in the syphilitic zone, mostly very slight. Of 53 cases giving a negative Wassermann reaction and no other indication of syphilis, 18, or 33.9 per cent., gave reactions mostly in the syphilitic zone. The authors maintain that a reaction in the syphilitic zone in cases of syphilitics does not necessarily argue syphilitic involvement of the central nervous system, all other signs being negative. It would seem to offer a differentiation of tuberculous meningitis, and is here at times more valuable than any other test. Four cases of tuberculous meningitis gave reactions not to be confounded with syphilitic disease.

51. **Salvarsan Therapy Based on Rapidity of Arsenic Excretion.**—The determinations made by Adler were 153 in number. The arsenic was found absent in the blood as early as twenty-four hours after intravenous injection. The majority of cases were found to be arsenic-free in from thirty-six to forty-eight hours after salvarsan injection. The longest interval after injection that arsenic was recovered from the blood was sixteen days in one case.

58. **Fundamentals in Infant Feeding.**—That the symptoms of indigestion show the cause, Ladd says, is true to a limited extent only. Fats, proteins and carbohydrates may all produce the same symptom-complex, for the reason that an indigestion caused by any one element, if uncorrected, results in a disturbance in the metabolism of all the elements. The general symptom-complex is vomiting or regurgitation, gas in the stomach or intestines with or without discomfort, failure to gain, or loss in weight, anorexia, fever or subnormal temperature, loose and undigested stools or constipation.

In indigestion due to fat, the vomitus is generally creamy and sour, with a strong odor of butyric acid. The examination of the stools shows fat curds, and soap stools which may be dry and crumbling or like clay. In severe cases they are oily.

In indigestion due to carbohydrates, which generally is associated with fat indigestion, if long continued the vomitus becomes more watery, the stools are acid and scalding, spongy or feathery, and show undigested starch with iodin. In protein indigestion the vomitus is cheesy, the stools contain tough curds. Putrefaction is especially liable to occur in such cases with foul stools and temperature. Mucus is simply a sign of irritation and may occur in the stools in all forms of diarrhea and indigestion. If present in large amounts and associated with continued temperature it generally means an infectious process. The presence of blood, pus and fever invariably indicates infection. Green stools generally represent the severer forms of diarrhea, which may or may not be infectious. They occur in all forms of diarrhea and infections, but the color is not important in the diagnosis of the cause. These points, Ladd states, should be borne in mind in the treatment of these conditions.

60. **Protein Content of Cerebrospinal Fluid.**—An analysis of the results obtained from 440 tests for proteins in the spinal fluid has convinced Bigelow that the determination of proteins alone is not very decisive in diagnosis, unless there is at least a trace of globulin or a large trace of total protein, when a syphilitic or parasyphilitic disease is indicated. Two rather striking points brought out are the large amount of globulin found in cases of paresis, and of albumin in many cases of senile dementia.

Taken in combination with physical signs and the results of other tests, however, Bigelow agrees that the protein estimation has considerable corroborative value. There are, too, certain conditions under which it is especially valuable, due to the fact that in syphilitic and parasyphilitic disease of the central nervous system it is much less subject to variation than are the other pathologic constituents of the cerebrospinal fluid, the cellular increase and complement-fixing substance.

In five cases of convulsive seizures in paresis Bigelow found a marked decrease in the cell counts, in three of them to the normal limit. But the protein does not show a corresponding diminution; there is even an increase, in most cases, which serves as a control from a diagnostic standpoint, on the cellular decrease. It is not very unusual to find a slight yellow tinge in the fluid from cases of paresis, and these yellow fluids always give very marked protein reactions. This color and increase of protein content are both explained by Bigelow to be due to slight hemorrhages on the surface of the brain.

80. **Pathology of Thrombo-Angeitis Obliterans.**—An acute inflammatory stage according to Buerger is an initial manifestation of the pathology of thrombo-angeitis obliterans. Certain purulent foci are developed, strongly suggesting the presence of some specific toxin, or, more probably, some microbial agent. The destructive influence of these foci is evidenced in their action on the angioblasts, whose true purpose is thwarted, the result being the elaboration of a morphologic complex, distinctive and characteristic for the disease. Just as in tuberculosis and doubtless in Hodgkin's disease, certain well-known structural products represent the specific reaction of the tissues to some organism, so here, too the changes are absolutely typical and diagnostic. Besides these changes, the production of aseptic blood clot plays a part in the development of the occlusive tissue; while the infiltration of the media and adventitia makes for the adhesive fibrosis in the deep vessels, and the distinctly palpable products of periphlebitis in the subcutaneous veins. The change of the acute into the healed connective tissue stage is rapid, a type of occlusion resulting which has for a long time been regarded as due to an "endarteritis obliterans."

82. **Anaphylaxis and Its Relationship to Immunity.**—Experiments were performed by Gurd in the hope of proving the possibility of immediate symptoms of intoxication following the introduction of transferred serum and antigenic protein without an intervening period of time. The fact that it has been possible to induce fatal reactions in this manner indicates that the fixation of receptors is not an essential step in the phenomena of transferred anaphylaxis. These experiments proved a period of incubation is not necessary in order that animals may become passively hypersensitive. The possibility of immediate transferred anaphylactic shock in Gurd's opinion indicates that the theory of parenteral digestion with liberation of toxic split products is the most reasonable explanation of the phenomenon of anaphylaxis.

The blood serum of "immune" animals contains anaphylactizing substances. Unless the immunity or insusceptibility of such animals be due to a purely cellular tolerance or other change, it should be possible to show that the serum of such animals contains substances capable of rendering sensitive animals immune. That this is the case was proved by a series of experiments in which it was shown that by varying the quantity of transferred serum introduced normal animals may be rendered either sensitive or immune. Similar effects of sensitization and immunization can likewise be produced when the transferred serum and the intoxicating dose of antigenic protein are injected simultaneously or immediately following one another. Thus is it proved that cellular fixation or other alteration in the introduced "antibodies" is not an essential feature of these reactions.

84. **Experimental Polyneuritis.**—When fed on an exclusive diet of white bread, whether with or without yeast Ohler noted that fowls develop a definite polyneuritis. When fed on an exclusive diet of whole wheat bread fowls remain perfectly well. To say, then, that any exclusive diet may cause symptoms of polyneuritis is not true to fact. Apparently, there is present in whole wheat bread not present in white bread some substance or substances essential to the health of the organism. In other words, it would seem that in the relation between whole wheat flour and highly milled white flour we are dealing with the same problem as in the relation between unpolished and polished rice. This problem arises, however, only when the diet is restricted and consists almost exclusively of white flour or polished rice, as the case may be.

85. **Chicken as Possible Typhoid Carrier.**—The work done by Mitchell and Bloomer seems to show that the chicken is highly resistant to the typhoid organism. It not only fails to take the disease, but also it cannot be made a carrier either by feeding the organism or by intravenous inoculation.

87. **Cultivation of Chick Tissue in Vitro.**—When combined the medium used by Smyth consists of egg albumin, 25; trypsinized peptone, 0.25; agar agar, 0.75; Ringer's solution, 74.

88. **Interrelationship of Dry Pleurisy, Pleurisy with Effusion and Empyema.**—Acute dry pleurisy, pleurisy with effusion and empyema Floyd claims to be steps in one process. The extent of pleural reaction is controlled by the virulence of the infection and body resistance. When the invading organism is one that excites little chemotaxis, pleurisy with or without an effusion will result, but if chemotactic action is profound and the elaborated toxin not too destructive, empyema results.

90. **Kidney Lesions in Psychopathic Subjects.**—In the series of 100 necropsies reported on by Southard and Canavan, no instance of normal kidneys was found. There were thirty-nine instances of acute renal disease and 11 of these complicated by a background of chronic lesions. There were 35 instances of chronic lesions. Clinically, among 65 cases examined, albuminuria was found in 25 (38 per cent.), and cylindruria in 18 (28 per cent.). The specific gravity went below 1.015 at times in 18 cases (28 per cent.).

Clinically, there were 10 instances of edema, probably either caused or favored by the renal condition (four of the 10 cases showed cardiac disease also). Clinical records show 19 instances of seizures or convulsions of some sort, but it is not clear how many of these can be regarded as renal. Clinical records also indicate that 23 of the 100 cases were regarded in life as more or less severe cardiac cases.

Of the females examined, 26 (or 52 per cent.) had borne one or more children. Thirty-two of the 100 patients were emaciated at death.

The most prominent gross lesion in the series was chronic interstitial nephritis, which occurred in 42 cases. Microscopically, chronic interstitial nephritis was found not only in these 42 cases, but also in 24 other cases (66 per cent.). In 33 cases chronic interstitial nephritis was not only marked in the gross but was the only significant kidney finding microscopically. Plasma cells were never found in such quantity as to suggest acute interstitial nephritis, but were found in 42 per cent. of the series. Thirty-eight of these 42 plasma cell cases showed the plasma cells distributed chiefly about the glomeruli. Eleven cases over 26 but under 50 years of age yielded plasma cells, the same percentage as did the total series. The occurrence of plasma cells in the kidneys of general paretics is worthy of note by reason of their constant occurrence in the brain. Seventeen of 30 paretics in this series showed plasma cells in the kidney (56 per cent.). Sixteen of the 17 paretics showed the plasma cells in the periglomerular region, while one showed them in a subcapsular zone. Seven of the whole series of 30 paretics had seizures; 5 of these seizure cases showed periglomerular plasma cells, one showed no chronic lesion except general fibrosis and one was a case of acute parenchymatous nephritis without chronic lesion. But 3 of these 7 cases showed casts and these only in one-tubule type (descending loop of Henle).

Twelve other non-paretic cases which had seizures or convulsions of various sorts failed to show plasma cells in the kidneys, but in eight instances did show casts, although always confined to a single-tubule type (six times in the descending loop of Henle). Seventy-three cases showed casts in one or more types of tubule; 50 cases in one type of tubule only (forty in the descending loop of Henle); 14 in two-tubule types; 7 in three-tubule types; and 2 in four-tubule types. Sixty-three of these cast-bearing cases showed the casts in the descending loop of Henle. Glomerular tuft changes of a serious nature occurred in 51 cases and there were indications of disease in 13 others (besides two acute lesions). Changes in the glomerular capsule were far less in number, being of a serious nature in but 17 cases (slight or infrequent in 10 others). Cast deposits occurred in 8 cases under 50 years of age without evidence of glomerular change.

92. **Anatomy of Pancreas in Diabetes.**—Fifty-four per cent. of the cases examined by Major showed normal islands of Langerhans. Fibrosis of the islands of Langerhans was present in 46 per cent. of the cases, but no more marked than in non-diabetic cases. In 46 per cent. of the cases there was some hyalin degeneration of the islands of Langerhans. This degeneration in only one case involved a very large number of islands. All of the cases showing hyalin degeneration also presented some fibrosis, and vice versa. The hyalin degeneration in the diabetic series was the most striking lesion present, and was encountered in only one case of the non-diabetic series. This non-diabetic case, however, showed more striking and extensive hyalin degeneration than any of the diabetic series. All the lesions of the islands found in diabetic cases were also encountered, and in some to a more marked degree in non-diabetics.

122. **Progressive Lenticular Degeneration.**—Nammack's patient was a male, the last of seven children. The family history was negative as to gout, rheumatism, syphilis, alcoholism or nervous affections. He had the usual diseases of childhood and at the age of 5 years he lost his speech and the power of walking, being obliged to creep around, but he was able to go to school at the age of 10, and left six years later in the fourth grade. He was always near the head of his class and liked to study. He had a bad temper and would get into quarrels with the other boys. He left school because his left arm began to shake so that he could not hold objects in it. After he left school he remained at home.

The first symptom of the disease occurred when he was 6 years old, when it was noticed that his left hand trembled considerably and that his right leg slowly turned in. The foot finally got into such a condition that he walked on the side of the foot and had to catch hold of bed-posts, etc., to support himself. There was no history of epileptic fits or periods of unconsciousness. Gradually, the tremor of the hand became more aggravated, the condition of the foot became worse and his speech became so nasal in quality that it was difficult to understand him. When he started to do anything he had to wait a few minutes and then quickly arose; as soon as he got up he would start swaying around and would have to take hold of some support to pull himself along. If he was in the open, without support, he would throw himself forward and drag or slide his feet. After he started walking he got along very well unless he stopped. The muscles of the arm and trunk were remarkably well developed.

The patient's facial expression was fixed; the mouth was large and drawn, and when walking or doing any form of exercise he protruded his tongue. He understood everything that was said to him and usually was in a jolly mood, although he had a bad temper. His intelligence was about on a par with that of a boy of 12 or 13. He was able to dress and to feed himself; only it took him longer. His condition had apparently remained unchanged for several months. Swallowing was normal. The tremor of the hand was coarse. The grip was good; the knee and ankle jerks were exaggerated; sensations appeared to be normal. The Wassermann test was negative. There was atrophy of the muscles of the right leg, hip and calf, with compensatory hypertrophy of the other muscles of the body.

123. **Dystonia Musculorum Progressiva.**—The subject of the case cited by Climenko was a girl 11 years old of Jewish parentage, the third child, born at full term after a perfectly normal labor. She was breast fed and began to walk and talk at about the age of 18 months. The bowels had always been irregular; her appetite was poor and she was frequently restless in her sleep. She played a good deal out of doors and was considered bright at school. When she was 9½ years of age she had an attack of whooping-cough. About a week or two after the attack she began to complain of weakness in her left lower leg. A little later the foot turned outward while running or walking quickly. The weakness gradually extended upward, and her knee gave way. Plaster-of-Paris applied to the knee joint seemed to relieve her a good deal. A few weeks later she began to complain of weakness in the opposite leg, and soon the left hand became involved, and with each attempt to use the hand it began to tremble. Similar tremors were also noticed in the lower extremities. She complained of no pain or paresthesias of any kind. The condition progressed steadily, and about a year after the onset of her symptoms she was no longer able to walk.

In the recumbent posture the patient showed a slight wormlike tremor of all the extremities, more pronounced on the right side. It somewhat resembled an athetosis but possessed a characteristic of its own, being somewhat irregular and worm-like and entirely lacking in rhythm. In the prone position there seemed to be a characteristic pose consisting of flexion of the right knee, with extension and external rotation of the right hip, and outward rotation of the left foot. There was a slight kyphosis in the lumbar region which became more pronounced in the sitting posture. On standing, a kyphoscoliosis was equally pronounced. The trunk assumed an acute angle, the pelvis varying in its position with movement. The patient could stand only with support. On standing, the right foot was at an unusual angle with the lower leg, the right knee assuming almost the shape of a genu recurvatum. The patient was unable to walk unsupported, a marked feature being a peculiar torsion of the trunk on the pelvis, the latter being thrown out of a normal angle relation with the trunk. On trying to walk there were numerous unskilful and disharmonious movements through extremities and trunk; to correct these movements, the patient seized her lower extremity at the joint, forcing it into proper position. The right hamstring and leg muscles were in a state of hypertonicity; almost rigidity. Both quadriceps groups and the left peroneal group were in a state of complete atonia. The hips were hyperflexed on the abdomen. Due to the atony of the flexors digitorum of the right hand, the fingers could be hyperflexed to such a degree that on dorsal flexion (really extension) of the fingers, they could be brought to an acute angle with the dorsum of the hand.

Both knee jerks were diminished, and the ankle jerks were obtained with difficulty. The Babinski andOppenheim signs were absent. The abdominal reflexes were present. All the various sensibilities were intact. The cranial nerves were normal. The heart, lungs and abdominal viscera showed no abnormality. The patient was able to write with difficulty. The electric reactions showed no qualitative changes, a hyperexcitability, however, was obtained in the hypertonic muscles. The urine showed a slight excess of indican, but was otherwise negative. The psyche was perfect. The roentgenogram showed that the neck of the left femur was shorter and thicker than the right and the sacrum was turned to the left. There was no change in the density of the bone.

143. **Treatment of Pectus Excavatum (Funnel Breast).**—The plan adopted by Taylor is to force the chest to expand and the ribs to rise to a normal level; and to do so often enough to overcome the rigidities, and allow the posterior muscles of the back and shoulder girdle to attain sufficient strength to maintain the heretofore dropped and collapsed chest in a normal position. He directs the patient to clasp hands behind and place them just below the shoulder blades, then to pull apart one against the other, extending both steadily downward, as far as possible, maintaining both traction and extension with increasing force, and to hold them at the end of full downward extension an appreciable time—a few seconds.

As an important detail, first the right hand clasps the metacarpal bones of the left hand, the fingers of the left hand remaining extended. The thumb of the clasping hand is *not* used; encircling the left hand twists the right and impairs the direction of pull. The movements are repeated, using alternate hands, one to clasp and one to extend; both being thrust down and pulled apart; also holding the back vertical, namely, not protruding the belly. It is sufficient to make ten extensions at a time—five with each hand—and daily at least for two or three months; then two or three times a week.

144. Abstracted in The Journal, Oct. 10, 1914, p. 1321.

146. **Hemiplegia and Aneurysm.**—Sixty days before Boston and Rummage saw this case, a man, 41 years of age, the patient while working was seized by an attack of severe pain immediately beneath the sternum, which preceded syncope. The pain subsided in approximately one-half hour, but following the disappearance of the pain, the patient noticed that he was unable to speak in his usual tone of voice. From the date of this attack his power of speech gradually lessened until aphonia supervened. Following the attack of syncope, previously cited, the patient experienced vague pains in the right arm and right leg. Hand in hand with the foregoing annoyances, there developed a harsh,

rasping paroxysmal cough, accompanied by profuse serous expectoration. Dyspnea was a conspicuous feature following the attack of syncope and progressed from bad to worse.

Three days before admission to the hospital, the patient, while sitting, was seized with an attack of vertigo and fell to the floor; consciousness was not lost. Until his admission and throughout his stay in the hospital, the patient displayed total inability to move the right arm, right leg, or right side of the face, features shown post mortem to be caused by cerebral embolism. The right half of the chest appeared to expand somewhat more than did the left during inspiration. The neck became markedly distended during paroxysmal attacks of coughing, and at such times there was an appreciable increase in the size of the veins of both the neck and upper portion of the thorax. There was incontinence of both urine and feces. Tracheal tugging was obtained.

The patient displayed arterial atheroma. The systolic blood-pressure remained around 160 mm. of mercury; diastolic 100 mm. Corresponding to the upper segment of the sternum was an area where the percussion note was appreciably impaired, and this area was imperfectly circular in outline, with a diameter of approximately 2 inches; at no time was there any undue evidence of pulsation or thrill over this dull area. A bruit was not audible over the side of the aneurysm.

Necropsy report: At the beginning of the transverse arch of the aorta was found an aneurysm about the size of an orange. This aneurysmal sac involved both the beginning of the innominate artery and a portion of the aorta beyond that point where the (innominate artery) blood supply to the right arm is given off. The aneurysm was fully two-thirds filled with well organized clot. A portion of the clot occupied the anterior surface of the aneurysmal sac, a pathologic feature which doubtless explains why abnormal pulsation was not detected in the sternal notch, and also why a bruit was not audible over the aneurysm.

181 Sanitary Control of Water-Ways. S. C. Highland, Clarksburg.

180. **Dementia Praecox Treated by Nuclein Solution.**—The patients treated by Keatley and Bobbitt were given calomel and laxative salines and a leukocyte count made. They were then started on intramuscular injections of nuclein solution. The formula used was that modified by Lundvall. They began with a dose of 1 c.c. and gradually increased it during the first two and one-half months to 10 c.c. and then increased or diminished it according to the reaction of the patient. The solution was injected deep into the muscles, using aseptic precautions. The reaction obtained was not as severe as spoken of by other authors. Only one patient had a chill after receiving 11 c.c.

There was no febrile reaction on the administration of less than 3 c.c. The reaction obtained on doses over this amount were distinct but not severe, the temperature rising from 99 to 101 F., the pulse rate being moderately increased and a feeling of malaise occurred in some cases. The first marked hyperleukocytosis occurred after the injection of 5 c.c. of the solution. The hyperleukocytosis ranged from 11,000 to 15,000 a few hours after administration of the nuclein, the count in one case being as high as 17,500. The polymorphonuclear neutrophils were found to be relatively increased. There was never any local reaction. There was an absolute lack of mental improvement in four of these cases. One case showed some temporary improvement which lasted only a short while. The administration of nuclein was discontinued because of the persistent loss of weight, with failing health and lack of mental improvement.

8. **Thyroid Extract in Certain Mental Disorders.**—For many years Goodall has employed thyroid extract in cases of stupor and stupor with melancholia, or of confusional insanity—cases which have certain features in common with myxodematous cases, but until the last two years the failures were more numerous than the successes. He attributes many of those failures to the circumstance that he gave insufficient doses of thyroid. His recent experience entirely justifies those who have insisted on large doses if any benefit is to follow. Thyroid is not only beneficial in acute stupor, or acute dementia, and "confusional" states, but also at a later stage of these conditions and of cases of recent melancholia, when the patient has improved to a certain point and there remained. In these cases administration of thyroid has appeared to complete the process of recovery.

Eleven patients suffering from such mental disorders were treated by this method. These patients were kept in bed during the whole course of treatment, usually in the open air, on liberal diet; and the temperature, pulse, and respiration were taken throughout twice daily. All had been mentally ill for months before the thyroid treatment was started. The amount of thyroid given varied from 25 to 50 grains a day for five to eight weeks. The pulse-rate was affected in the direction of increase very consistently, whereas the temperature and respiration were affected but slightly, or not at all. Gain of weight during the treatment occurred in two of eleven cases; one showed no change; in all the others a loss was noted, but after cessation of treatment weight was rapidly regained, and in eight instances there was ultimately a gain on the original weight. The results were highly satisfactory, since no less than six patients of eleven became well; and all the others, except one, showed a definite improvement, and this one had been deranged for no less than three years when treatment was employed.

In eleven out of twelve cases of epileptic insanity treated with thyroid the number of fits was reduced. The patients were not on any other drug, but were kept in bed on ordinary diet with, in some cases, extras, such as milk and egg. A reduction of weight occurred in all except one. The observation as to the pulse, respiration, and temperature made in connection with the first series of cases apply also to this series. On the basis of these results Goodall kept certain of these patients on 5 grains of thyroid daily for a prolonged period; the patients were up as usual and on their usual diet. A substantial reduction in the number of fits occurred in many of these cases, amounting in some to from 52 per cent. to 65 per cent., as a result of a small daily dose of thyroid. No ill-effects were observed.

9. **Case of Leprosy Treated with Radium and Diathermy.**—Three facts are specially worthy of note in Iredell's case of maculo-anesthetic leprosy: (1) that the patient is better in all respects than he was six months ago; (2) that his improvement began when diathermy was started, and (3) that he felt better directly after each treatment. The disease in his case has been characterized by (a) macula, (b) two lepromes, (c) neuritic affections, and (d) intestinal trouble. (a) These were the symptoms of the first stage of the disease and passed off before treatment was begun. (b) A leprome on the cheek disappeared spontaneously; that on the lip was not treated with diathermy, and therefore it cannot be said what the effect of diathermy would have been, but it certainly seemed to respond at once to radium treatment. (c) The effect of diathermy on the patient's ulnar nerve was remarkable. For some time he had been in the habit of putting his arm in a hot bath in order to ease the pain. After holding two electrodes in his hands for twenty minutes the pain in the arm was far more relieved than it had been by the hot baths, and he found that he was able to move the little finger better than he did before. Some twinges of the left external peroneal nerve cleared with one application. (d) No less striking than the effect of the treatment on the nerves was the effect on the abdominal trouble. While the treatment was in progress peristalsis was distinctly perceptible to the patient, and in the course of the twenty-four hours following, very copious evacuation occurred, although no drug was used. This in marked contrast to what had happened in the first three attacks, when it was found necessary to use aperients. Since April, when the treatment started, he has had five treatments at intervals of a few weeks, and on two occasions he had treatment daily with corresponding benefit.

11. **Glycerin in Bromidrosis.**—Of five cases treated by Benians three were of a mild type associated with the warm weather. These were completely relieved while the treatment lasted, but relapsed when it was discontinued. The other two cases were of a severe type. The condition had persisted for some months in spite of energetic measures taken to insure cleanliness, and despite the continued application of drying and disinfectant powders. In both of these two latter cases there were blisters and abrasions, and in both cases the condition was completely cured in the course of three days by the application of glycerin well spread over the soles and toes before the socks were put on, this being repeated each morning as long as was necessary (three times in both cases).

17. **Case of Traumatic Carcinoma of Breast.**—The following case is of interest, for it is the first in which the doctrine of traumatic carcinoma has been accepted in the English high courts. A woman consulted Handley on March 26, 1912. She stated that on Nov. 3, 1911, she fell over a beam, where building operations were in progress, landing on the left elbow and the left breast. The arm had to be kept in a sling for three weeks, and subsequently its movements were stiff. About Jan. 1, 1912, she first noticed a discharge from the left nipple, and shortly afterward a small lump was noticed in the left breast. Ever since the accident her general health has been impaired. On examination Handley found the upper half of the left breast occupied by a large and advanced malignant tumor, extensively adherent to the overlying skin. The tumor appeared to be a rapidly-growing one. It was removed by him April, 1912. Examination of the growth showed it to be a rapidly growing duct-carcinoma, evidently of multifocal origin, for it mapped out accurately the anatomic limits of the group of lobes forming the upper hemisphere of the breast.

24 *Relations between Meteorologic Conditions and Air-Borne Epidemic Disease. A. Trillat.
25 *Morphin for Painless Delivery. (Sur l'emploi de la morphine comme analgésique.) G. Bertrand.
26 *Medicated Gauze for Dressing Wounds in War. (La gaze au trioxyméthylène.) Pauchet and Sourdat.

24. **The Weather and Air-Borne Infectious Disease.**—Trillat has been studying epidemics in connection with meteorologic conditions and has found that the faculty possessed by micro-organisms of serving as a nucleus for

condensation of moisture is an important factor in the spread of infection. When numbers of micro-organisms thus serve as surfaces for condensation of moisture, they form a moist dust which obeys physical laws quite different from those which govern dry dust. The size of these microbian droplets and the time required for them to settle down in quiet air are dependent on the size of the germs, and gravity aids in sifting out certain ones from the crowd of droplets. When smaller than a micron in diameter they escape the action of gravity and obey only the laws of thermodynamics, being swept along and separated by air currents and attracted instantaneously to a cold region or surface. The attraction of the cold area or surface is felt and yielded to even against a current of air.

Microbes thus suspended in droplets in the air are extremely sensitive to favoring or antiseptic influences. The gases of respiration or of vegetable or animal decomposition transform each of the droplets into actual microscopic culture media. In certain circumstances a volume of humid and sterile air can be inoculated throughout by the introduction of such microbian droplets. The connection between epidemics and meteorologic conditions, wind, heat, low atmospheric pressure, electric conditions, etc., is thus evident. The microbian droplets can be carried for considerable distances by the wind and then, under the influence of sudden cold, be instantaneously localized in a region, without losing their biologic properties. The fact that this can occur also against the prevailing wind explains the capricious course of certain extensive epidemics of disease transmissible by the air. Other causes may cooperate in the assembling and sifting out of the microbes, especially whirling eddies of air. The action of electricity is complex. In the formation of ozone it exerts an antiseptic action, while, on the other hand, the ionization of the air promotes the condensation of moisture and the formation of droplets. Low barometric pressure permits the escape of gases stored in the soil and elsewhere and these facilitate condensation and multiplication of pathogenic germs. He suggests that this may be one factor in making a soil a tetanus-breeder.

25. **Morphin for Painless Delivery.**—For editorial comment see The Journal, Dec. 19, 1914, p. 2233.

26. **Trioxymethylene Gauze for Wounds in War.**—Pauchet and Sourdat have found that the best of all dressings for the wounded soldiers is gauze impregnated with paraformaldehyd. It is not only aseptic but it sterilizes and fastens the tissues with which it comes in contact, and the wound seems to dry up without oozing or suppuration. There is no need for asepsis in preparing the gauze. It is placed in a tin box or other covered vessel and a few tablets of trioxymethylene (paraformaldehyd) are placed in the bottom of the box and it is then set near a stove or radiator (about 50 C.) for an hour. In case of a seton wound, they cut the bridge of tissue and pack the groove with this medicated gauze with a dry dressing over it. Wicks of the medicated gauze are introduced into the depths of the tissues in case of a compound fracture, leaving the splinters of bone and the tissues unmolested as much as possible. The effect is a kind of embalming and with the limb thus treated, and splinted the wounded man can stand a long journey. Even after amputation for gas gangrene, treating the stump with this medicated gauze facilitates rapid healing. It should never be applied after tincture of iodin as it is liable to prove irritating, but under other conditions, they have found it incomparably better than any other method at their command for dressing wounds in war. The dressing does not have to be renewed generally until the fifth day.

31 *Physiologic Occurrence of Arsenic in Human Organs, Especially in Women. V. Frommer.
32 *Puerperal Tetanus. R. Spiegel.

27. **Eclampsia.**—Schüppel describes a case of total necrosis of the cortex of both kidneys found at necropsy of a woman of 35 who had succumbed to puerperal eclampsia. The findings indicated that eclampsia may be the result of excessive destruction of the formed elements of the blood from injury of the liver or kidney during the pregnancy, thus checking the normal elimination of the waste products of the placenta. The wreckage of the formed elements thus destroyed in excessive amounts blocks the finer vessels, and the shape and size of the vessels in the kidney cortex render this a particularly serious matter here, the circulation through the whole cortex thus being soon shut off completely. Any therapeutic measure, even decapsulation of the kidney, would be entirely useless in such a case.

28. **Leukemia in a Pregnant Woman.**—Petersen recalls that Hermann in 1901, commenting on eight cases he had compiled, remarked that the enlargement of the spleen and liver in leukemia causes greater disturbance of course when the uterus is distended, so that the symptoms from leukemia are more severe in the pregnant. Abortion is also more common, but if the patient survives the abortion or miscarriage the condition materially improves thereafter. French in 1908 reiterated that the prognosis in leukemia is far graver in the pregnant than in the non-pregnant. He knew of seven cases on record, and Petersen states that no instance was known among the 22,000 obstetric cases at the Breslau Provincial Maternity until recently a woman of 24, nearly at term, was sent there in a serious collapsed condition with the presumptive diagnosis of leukemia. The spleen was not much enlarged and the blood did not show the characteristics of either leukemia or pernicious anemia. But necropsy revealed the changes in the organs typical of myeloid leukemia, and apparently confirmed the assumption that the leukemia had developed at the fifth or sixth month of the pregnancy. This was the case likewise in Greene and in Hilbert's cases, and the fatal collapse following spontaneous delivery was duplicated in these cases and also in one reported by Laubenburg in 1891. Petersen advises immediate interruption of the pregnancy as the only possible treatment when a woman known to be leukemic becomes pregnant, as also when leukemia develops in a pregnant woman. The earlier it is done the better. The child seemed healthy, showing no signs of leukemia at the time or since. Saenger and Cameron have also reported similar experiences showing that the child of a leukemic mother is not necessarily itself leukemic.

30. **Anesthesia in Gynecology.**—In this third part of his article Schlimpert describes his study of general anesthesia from nitrous oxid, comparing the various technics in vogue alone or combined with other anesthetics. Until recently it has had very little vogue in countries other than the English-speaking, but lately has been taken up with new interest in other lands. His extensive experience with lumbar anesthesia has convinced him that even with the most painstaking technic we must reckon with a certain proportion of refractory cases and a certain number of cases with persisting after-headache.

31. **Arsenic in Human Organs.**—Frommer has been investigating to learn what becomes of the arsenic entering the body in the food and normally eliminated in the urine and menstrual discharge. During pregnancy this elimination is impeded, and his theoretic assumption that arsenic is thus retained during pregnancy was confirmed by his research on rabbits, human fetuses and the organs from pregnant cadavers, including two cases of eclampsia, and in some male cadavers. The organs of one young man who had succumbed to Banti's disease showed quite a large proportion of arsenic. It was positively known that he had taken no arsenic during eight months at least before his death. In all the organs examined arsenic was found in amounts

ranging from traces to considerable proportions (*starker Arsenspiegel*). The effect of so much arsenic on the physiologic processes must not be disregarded any more than its importance from the medicolegal standpoint.

32. **Puerperal Tetanus.**—Spiegel adds four cases from his own practice to the sixty-two he has found in the literature in which tetanus developed soon after an abortion or birth of a child. In only one of his cases was the correct diagnosis made at once. He tabulates the details of the entire list and comments that early diagnosis and intravenous and intraspinal injection of antitetanus serum are the main reliance, clearing out the focus by rinsing and curetting the uterus. For this 70 per cent. alcohol seems to give the best results, as the tetanus toxin is precipitated by alcohol, and the spores deprived of their toxin are less dangerous. He advises tamponing the uterus with antitetanus serum, renewing the tampons each day; if the cervix is not dilated, daily rinsing with alcohol may suffice. Of all symptomatic measures to arrest the spasms, intraspinal injections of 5 or 10 c.c. of a 15 per cent. solution of magnesium sulphate seem to be most effectual. The patient's strength must be kept up with nourishing food. The conditions in the puerperal uterus favor absorption so that the incubation phase is comparatively short.

39 Febrile Reaction and Hemoptysis after Diagnostic Injection of Tuberculin. (Fall von Tuberkulinschädigung bei der diagnostischen Anwendung des Tuberkulins.) Brösamlen.

33. **Improved and Uniform Technic for the Skin Tuberculin Reaction.**—Frehn emphasizes that the skin responds differently to the tuberculin test in different regions, and that it is important to choose the point responding most sensitively to the test and keep to this one point. Otherwise the reactions cannot be compared. The conditions in regard to the skin itself and the local blood and lymph circulation seem to be most favorable in the chest. He thinks that far more instructive findings than those hitherto obtained can be realized by testing to what extent the organism can be sensitized by the Pirquet skin test applied with 50 per cent. tuberculin. The test is then repeated with 5 per cent. tuberculin and again, exactly eight days later, the test is made again with the 5 per cent. tuberculin. He applies the test on both sides of the sternum each time and takes the average between the size of the two papules in square mm. As a rule, the second and third local reactions are much more pronounced when the resisting powers of the organism are at par or above. The reaction grows less and less pronounced the more seriously the organism is diseased. This double inoculation method, based on the sensitization which occurs in the vigorous from the first inoculation, seems to promise much greater accuracy and more instructive findings than with the ordinary technic. Frehn tabulates the findings in 33 clinically healthy, 94 per cent. demonstrating marked sensitization; in 36 patients in the first stage of tuberculosis, with evidence of sensitization in 71 per cent.; in 30 in the second stage, 43 per cent., and in 39 in the third stage with only 28 per cent. sensitized. The index is the quotient of the size of the papules from inoculation with the 5 per cent. tuberculin. All the clinically healthy persons tested had been in more or less contact with tuberculosis, and only 3 of the 34 gave a completely negative response to all the inoculations.

The first papule of one patient of 29 measured 73 square mm. with the 50 per cent. tuberculin; the second papule, with the 5 per cent. tuberculin, measured 8 mm. and the third 400. The index in this case was therefore $400 \div 8 = 50$. The highest index in this group was in a patient of 24 whose papules measured, respectively, 32, 0 and 157. His index was thus $157 \div 0 = 157$. The lowest was in a man of 28 with psoriasis and the build suggesting a predisposition to tuberculosis. His figures were 81, 28 and 68, with index of 2.4.

In the cases of actual tuberculosis (first stage), the figures ranged from the series, 8, 7 and 12 (with index of 1.7), to 233, 231 and 262, with index of 1.1. In none in this group was the index over 4.1, and in all but 3 it was below 2. In 9 it was below 1. In the 30 in the second stage and the 39 in the third stage, the index was below 2 in all but one case and below 1 in over 50 per cent. Typical figures for the papules in these groups were 263, 62 and 53; index 0.9, and 178, 101 and 45; index 0.5.

The index in the four groups averaged 20.1; 1.6; 1.4, and 1.2. One important practical conclusion from Frehn's work is that the prospect for tuberculin treatment is most promising when sensitization seems to be most pronounced.

42. **Limitations of Organotherapy.**—Münzer emphasizes that no organ works independently. Each acts on others and is acted on by others so that it is futile to hope that administering the extract of one organ will take the place of the organ in the general phenomena going on. A dead preparation can never take the place of a living organ. The only real organotherapy, he insists, is the transplantation of a sound organ in the place of the diseased one. Everything else in the way of organotherapy is but a makeshift.

53. **Research on the Coronary Circulation.**—Morawitz and Zahn describe in detail their studies of the coronary circulation in living animals and give tabulated results. The quality of the circulation in the heart muscle seems to be dependent on the arterial pressure. Any increase of arterial pressure by abdominal compression, infusion of blood or salt solution and epinephrin increases the flow of blood from the coronary vessels. Epinephrin also has a direct dilating effect on the coronary vessels. It is by far the most effective means of increasing the circulation through the heart muscle. In spite of that it does not seem to be effective in human angina pectoris. Quickened heart action produces unfavorable conditions for the circulation in the heart muscle. Stimulation of the accelerans cordis dilates the coronary vessels; stimulation of the vagus decreases the dis-

charge of blood from them. Pituitary extract and nicotin contract the coronary vessels. This vasoconstriction can sometimes be demonstrated in spite of the increased blood-pressure.

67 *Bone Cysts. (Pathogenese der sogen. Knochencyste.) J. Bolognesi.

63. **Juvenile Deforming Osteochondritis.**—Brandes reports ten cases with the Roentgen findings and remarks that the cases of supposed tuberculous hip-joint disease with recovery may have been merely cases of this comparatively benign affection, juvenile deforming osteochondritis. (See The Journal, May 2, 1914, p. 1444, abstract 174). Ankylosis does not seem to occur in this affection. He applied a walking plaster cast for two or three months, materially improving conditions so that afterward there was much less limp.

64. **Acute Necrosis of the Pancreas.**—Jenckel reviews his experience with acute necrosis of the pancreas in nine cases, all men but three. The youngest was 28, the oldest 75. With one exception all were well nourished and inclined to corpulency. There was gall-stone trouble only in three of the cases. In three other cases the necrosis developed after a laparotomy. With severe clinical symptoms an operation is indicated without delay, but temporizing is justified if the symptoms are mild and the bowels move after one or two enemas, and the pulse keeps good and not much accelerated —when these conditions are encountered dietetic measures alone may bring relief. The cases reported demonstrate anew that slight attacks of a similar character had occurred before and passed harmlessly over. Even a very severe form may spontaneously retrogress, as in one of his cases, but this is so rare it should not be counted on. Operative treatment can cure only when the toxic action has not been too severe and the further progress of the necrosis can be checked.

67. **Pathogenesis of Bone Cysts.**—Bolognesi reports entirely negative results from his experimental research on the origin of bone cysts. Neither with trauma nor with an infectious process was he able to induce the formation of a bone cyst.

71 Inflammation of the Accessory Cavities of the Nose as Complications of Scarlet Fever. (Nebenhohlenentzündungen der Nase bei Scharlach.) M. Paunz.

69. **Changes in the Myocardium and Heart Ganglia in Scarlet Fever.**—From an examination of forty-nine cases Stegemann comes to the following conclusions: In severe toxic cases of scarlet fever of short duration, the parenchymatous changes in the heart muscle are slight. In the infectious form of long duration, in addition to acute parenchymatous degeneration, there are fatty degenerations and necrosis. Interstitial round-cell infiltration of the heart wall is lacking in the short severe toxic cases, but is always present in the long infectious cases. In the stroma of the heart ganglia, round-cell infiltration can be demonstrated in the first days of the disease; its intensity is dependent on the severity and duration of the disease. Fatty degeneration and necrosis of nerve cells were observed on the first day of the disease. The number and size of the Nissl bodies were markedly decreased in the severe toxic cases, in contrast with the infectious cases. These facts' seems to show that in the severe toxic cases of scarlet fever, of short duration, the cause of the heart weakness lies in pathologic changes in the heart ganglia. The nervous theory of the origin of the heart disturbance in scarlet fever has gained ground recently at the expense of the myocardial theory.

82 *Differential Diagnosis of Chronic Appendicitis. C. W. Bischoff.

82. **Differential Diagnosis of Chronic Appendicitis.**—In 1911 Bastedo proposed a method of differential diagnosis of appendicitis: A rectal tube is introduced into the previously emptied intestine, and the colon filled with air. If the appendix is diseased, the patient feels a sharp pain in the region of the appendix, sometimes radiating to the umbilicus. If the appendix is normal, there is no pain, but only a feeling of distention, or sometimes an unpleasant sensation between the umbilicus and the symphysis. Of course, overdistention should be avoided; the sign is elicited by moderate distention. To test the value of this sign, Bischoff tried it in a series of thirty-seven laparotomies. In twenty-three of them Bastedo's sign was present; in all these cases there was chronic appendicitis of the most varied forms, adhesions to the neighboring tissues, contraction of the mesenteriolum, kinking, stenosis, fecal calculi or oxyuris. In fourteen cases Bastedo's sign was not present, and in these cases the appendix was found normal. Particularly interesting were six cases in which the right adnexa were diseased, and in which Bastedo's sign furnished a differential diagnosis from appendicitis. Another interesting case was one of cholelithiasis All the symptoms were those of appendicitis, pain at McBurney's point, stomach symptoms, pain in the region of the umbilicus, etc., and there were no decided symptoms of cholelithiasis. Bastedo's sign was negative, and the appendix was found absolutely normal.

Distention of the colon is also valuable in differentiating between appendicitis and neuralgias. The latter are frequently found in gonorrheal patients and often cause pain at McBurney's point. Pain at McBurney's point should not be so much emphasized as a sign of appendicitis, for it is often found in other conditions. Rost asserts that Bastedo's sign is positive not only with disease of the appendix, but also in pathologic conditions in the colon. Bischoff has no data on this subject. Rost says, too, that the pain appears only if there are changes in the mesenteriolum which bring the appendix into a certain abnormal relation to the cecum, but Bischoff found it positive when the mesenteriolum was entirely normal and the appendix alone was diseased. In the cases that he examined after operation there was no longer the slightest pain in the appendix region when the colon was distended.

89. **Cosmetic Depilation.**—Chilaiditi applies the Roentgen rays to the just sprouting hair and thus kills it. The hairs are pulled with tweezers and, two or three days later, the papilla is exposed to the rays filtered through 3 mm. aluminum plus 5 mm. leather. He says that the papilla and the hair as it first sprouts are most susceptible to the rays during this period of intense growth. A single sitting answers the purpose. The dose must be about 15 Holzknecht units, enough to induce a just visible reaction of the first grade.

90. **Infection of the Fetus.**—Masay experimented with the *Streptobacterium fetidum* injecting gravid guinea-pigs with it. The placenta was no obstacle to its passage into the fetus, and it actually seemed as if the fetus served as a kind of "fixation abscess," the germs congregating in it and forsaking the maternal organism. Two hours after the injection of the germs they were evident in the fetal blood. Emptying the uterus thus clears out the hosts of germs that have congregated in the fetus. This suggests that abortion is a natural phenomenon of defense. It is possible that the germs in the maternal organism may go at once to the fetus apparently without infecting the mother.

91. **Mechanical Devices for Correction of Writer's Cramp.**—Meyer treats the spastic forms of writer's cramp by having a hollow cast made of the hand in the proper position for writing. It forms thus a kind of rigid half glove fitting over the fingers and holding them immovably in the proper position for writing, thus preventing any spastic contracture until the hand outgrows the tendency. He gives illustrations of the cast made in two cases and used with complete success.

92. **Tetanus.**—Six articles are devoted to this subject, relating experiences with tetanus among the wounded. Hochhaus has had 46 cases, Kreuter 31, Rothfuchs and Alexander 10 and 8. Müller has found long hot baths a remarkable relief for the patients, and Rothfuchs reports benefit from salvarsan in 4 cases. Some claim great benefit from magnesium sulphate; others have nothing good to report from it. Alexander states that his 8 patients given 10 gm. of chloral in a single dose each day have all recovered; 2 given only 5 gm. died. Müller comments on the extreme relief afforded by tracheotomy in some cases. One of his 2 tracheotomized patients is apparently recovering. The other succumbed to weakness of the heart after subsidence of the tetanus.

97 Vaccination against Typhoid. (Die Schutzimpfung gegen Typhus abdominalis.) H. Braun.
98 *Treatment of Tetanus. G. L. Dreyfus.

96. **Injury from Vaccination.**—Göppert has made a point in the last few years of following up every case of alleged injury resulting from vaccination, and states that he has found cases which imperatively teach a lesson of caution in certain respects. This is especially important in case of chronic eczema; the slightest trace of chronic eczema should cause the child to be excluded from vaccination for another year, even if six months have elapsed since the eczema was apparently cured. This should be the rule also if there is any case of chronic eczema in the family. Even a year after the healing of the eczema may be too early to do the vaccination. In regard to secondary infection he remarks that as erysipelas is far more serious for infants under 6 months old than later, children should not be vaccinated until they are over 5 months old. The scab in the second or third week is liable to come off, leaving a point of lesser resistance and inviting erysipelas. Children also with acute or chronic digestive disturbances or unstable convalescence from acute, recurring or chronic intestinal catarrh should be scrupulously excluded from vaccination. Some children react to every slight cold with fever or diarrhea, and when such troubles develop after vaccination they require suitable treatment not to be allowed to drag along. Copious intake of water should be enforced in particular. He adds that profuse sweating softens the skin and predisposes to furunculosis, etc., so that this is another reason for preferring to vaccinate outside of the heated term.

He covers the vaccinated region with medicated gauze held in place with strips of plaster with spaces between, or a perforated plaster. If there is much pain and restlessness or the axillary glands are swollen, he dresses the region with aluminum acetate after smearing with petrolatum. For this he cuts a slit in the center of a square of several thicknesses of gauze, 30 sq. cm., and has the arm slipped through the slit. The gauze is then drawn up and fastened to cover the arm and axilla. The dressing should be changed every twelve hours. The mother who brings the child for vaccination should be asked whether the child has been sick recently or has ever suffered from diarrhea or eruptions, cough or convulsions, and whether any one else in the family is sick. When vaccinating on a large scale, it is better to have the entire trunk exposed for examination, and any suspicious findings call for detailed investigation later. He adds that the ninth or tenth day is better for the reexamination than the seventh day, as any complications are then at their height as a rule.

98. **Tetanus.**—Dreyfus has already encountered twenty-four cases of tetanus among the wounded in the Frankfurt hospitals, and remarks that 500 cases developed among the wounded after the battle of Mukden in the Russo-Japanese war. In the Prussian army during the last twenty years of peace there have been only ninety-six cases. He emphasizes the vital necessity for local treatment of the wound and for avoiding anything which will cause the formation of a scab.

102 Impressions in a Field Hospital. (Erlebnisse und chirurgische Erfahrungen aus einem deutschen Feldlazarett.) *R. Mühsam.*

101. **Harmless Diabetes in the Young.**—Frank refers to the form known as renal diabetes, that is, without abnormal proportions of sugar in the blood. The more often the blood is examined for sugar as a routine diagnostic measure, the

more numerous such cases are becoming. The glycosuria of pregnancy is probably of this type. The trouble is not the result of injury of the organs regulating the metabolism of carbohydrates, but merely some functional disturbance of the kidney epithelium, traceable to some slight injury, possibly an overfunctioning. There is scarcely any probability of this renal diabetes becoming transformed into severe diabetes with large losses of sugar and acidosis. Weiland, Boenniger and Salomon have each reported cases under observation for five or ten years in which the syndrome kept stationary or improved. Transformation into actual kidney disease has never been observed, according to the literature on the subject. Only the condition known as pregnancy kidney may be regarded as the rarely occurring second phase of renal diabetes. There is none of the complications of ordinary diabetes, such as neuritis, pruritus, furunculosis, cataract, retinitis or falling out of the teeth, as the proportion of sugar in the blood is not pathologically high. There is no need for dietetic restrictions, and the renal diabetes may be regarded as a harmless anomaly in examining for life insurance.

104. **Venereal Disease and War.**—In the course of his long study of this subject, Finger states that even on a peace footing there is a daily average of 1,748 men under treatment for venereal disease in the Austrian army. During war time the proportion usually increases as he shows by statistics from one army corps in the Franco-Prussian War (first Bavarian): in 1871 the proportion ran up from 10.2 per thousand in January to 77.7 per thousand in May. Extensive epidemics in various districts followed the disbanding of the troops at the close of that war.

110. **Rickets and Internal Secretion.**—Rominger examined forty-one children and six normal adults by Abderhalden's method to determine whether any disturbance of the glands of internal secretion could be demonstrated in rickets. Twenty-eight of these individuals were rachitic and nineteen clinically free from rickets. He could not get uniform results in either the rachitic or non-rachitic cases, and concludes that the protective ferment reaction is not specific. No disturbance of function could be demonstrated by the Abderhalden method in the thyroid, thymus, ovary or testicle. Deutsch has claimed that there was almost always a regular digestion of thymus tissue by normal sera, but Rominger could not confirm this. He does not believe that Abderhalden's dialysis method can be utilized for the examination of the function of organs. It remains to be seen whether Griesbach's proposed quantitative determination of the albumin in the dialysate can be utilized for this purpose.

111. **Pathogenesis of Digestive Disturbances in Infancy.**—In overfeeding and decomposition of foods volatile fatty acids are formed that may be regarded as hypothetical toxins. Bahrdt and Edelstein have previously published papers in which they discussed the methods of determining these acids, and their effect on the intestine and on metabolism in animal experiments; also determination of them in the stomach contents and stools of infants. This paper takes up the examination of various foods with reference to their content in such acids—fresh milk, buttermilk and "spoiled" milk, containing various kinds of bacteria. They fed dogs with milk containing pure cultures of many different kinds of bacteria. After two hours the dogs were killed and the stomach and intestines examined for bacteria and for fatty acid content. They come to the conclusion that milk, even when infected with pure cultures of bacteria, does not form, within the first few days, sufficient quantities of volatile fatty acids to produce acute digestive disturbances. These facts indicate that spoiled milk does not play the preponderant part in the ordinary acute summer diarrheas of infants. The question they are trying to decide is whether these disturbances are caused by substances in the food or by changes in the chyme in the infant's body. Having determined that they are not caused simply by bacterial infection of milk, they intend to take up further experiments to find whether infected milk will produce worse effects if given in conjunction with conditions that interfere with the motor and secretory functioning of the stomach, such as heat and overfeeding. The details of their experiments are given in tabulated form, and there is an extensive bibliography.

120 *Phenol-Camphor in Treatment of Infectious Processes. (Kurze Bemerkung zu der Originalmitteilung von Schiele.) G. E. Konjetzny.

119. **Forward Dislocation of the Clavicle.**—Braatz found that the dislocation recurred after reduction when the shoulder was drawn backward in the case reported. To prevent this, he bandaged the shoulder, pushing it forward and holding it in this pushed-over position with a hard pad of cotton at the back of the joint, held in place with strips of adhesive plaster and other bandages to keep the shoulder thus pushed forward. The clavicle and shoulder were kept immobilized in this way for two months and conditions have persisted normal since. This answers the purpose as well as Danielsen's method (described recently in these columns, Nov. 21, 1914, p. 1827), while it is far less inconvenient.

120. **Phenol-Camphor Treatment of Suppurating Process.**—Konjetzny says that he has been using this method of treatment for years for purulent phlegmonous processes and with good results. Chlumsky's original formula seems to him the best. This is 30 parts liquefied phenol and 60 parts triturated camphor with 10 parts alcohol. It is especially useful in pyocyaneus infection and tetanus, but there is danger of phenol poisoning if used too profusely in large cavities. He moistens gauze with the solution, wrings it out and covers the lesion with the gauze. He says we must not rely too implicitly on the alleged paralyzing of the phenol by the camphor.

122 *Ultimate Outcome after the Schauta-Wertheim Operation for Prolapse of the Uterus. E. Clauss.

122. **Treatment of Genital Prolapse by Interposition of the Uterus.**—Clauss has compiled the statistics in regard to the Schauta-Wertheim operation for prolapse, repairing the pelvic floor with the uterus itself. Recurrence of the prolapse occurred in from 2.9 to 20 per cent. of the cases, and pregnancy followed the operation in two cases at Hamburg last year although the technic was supposed to have rendered this impossible. Further modifications are here proposed which will effectually sterilize beyond question. This method should never be used unless the woman is over 35 or 37 or already has several children or conditions are exceptionally serious. The history of 51 out of 62 cases is known for two to six years since the operation was done at the Hamburg clinic in question. A complete cure was realized in 72 per cent. In 7 others besides the 37 in this group the patients were free from all subjective disturbance but the anatomic conditions were not perfect. The improvement thus realized in 86 per cent. of the cases compares favorably with the results of other methods. One patient succumbed to sepsis; this case teaches the importance of healing up all old lacerations and erosions before attempting the Schauta-Wertheim operation.

132 *Nervous Diseases; 5,000 Dispensary Cases. R. Colella and B. Frisco.

132. **Nervous Disease at Messina and Palermo.**—Colella and Frisco found in 54 per cent. of the 5,000 cases reported that syphilis, alcoholism or tuberculosis in the parents was an important factor in the nervous diseases encountered. Only 20 per cent. were found free from signs of tuberculosis or syphilis. In 10 per cent. there were signs of both; in 40 per cent. tuberculosis alone and in 30 per cent. syphilis alone. Among the children with nervous affections, the tuberculin reaction indicated tuberculosis in 61.7 per cent.; syphilis in 23.8 per cent. and both of these in 14.7 per cent. Among 430 inmates of the Palermo Insane Asylum, the Wassermann reaction was positive in 18 per cent. Consanguineous marriages are also a factor in the nervous diseases; the parents were closely related in 30 per cent. of the 5,000 cases. Exophthalmic goiter was also frequent (92 cases) and goiter with secondary disturbances in 125 cases. The influence of heredity was particularly marked here; in some families the mother had had exophthalmic goiter before her marriage and some of the children developed it at an early age. They add that all these cases of simple and exophthalmic goiter came from one district with a single water supply. There were 123 cases of infantile spinal paralysis; they thus formed 21.7 per cent. of the 453 cases of spinal nervous affections. Tabes is comparatively rare, considering the prevalence of syphilis. Epilepsy is quite prevalent in Sicily; it formed 10 per cent. of the 4,276 patients with nervous disease, while neurasthenia was observed in 15 per cent. and hysteria in 11.8 per cent. The food, the lime in the water and the lack of exercise seem to be responsible for the unusual prevalence of the gouty diathesis in men and obesity in women.

Hospitalstidende, Copenhagen

133 *Fat Tissue as Filling for Cavities in Bones. (Plombering af Knoglekaviteter med frit transplanteret Fedtvæv.) I. Svindt.

133. **Fat Filling for Bone Cavities.**—In Svindt's three cases the large flap of fat tissue was taken from the buttocks to plug a cavity left in the tibia after a process of syphilitic or tuberculous osteomyelitis. The patients were up in two or three weeks. The rapid healing and the perfect cosmetic effect are great advantages of this technic. The patients were two young women and a boy of 10. The largest chunk of adipose tissue, taken from the buttocks, measured 12x3.5x3 cm.; the next 9x2.5x3 cm., while the boy's flap was 6x2x2.5 cm. Each healed in place by primary intention and without reaction as the cavity was sterile; this method is scarcely applicable if there is still active infection in the focus. Its field is for old torpid lesions, such as syphilitic and ossifying osteomyelitis. Fistulas and secondary infection naturally contra-indicate it. Tuberculous processes can be treated in this way only when it is certain that all the diseased tissue can be removed.

Svenska Läkaresällskapets Handlingar, Stockholm

XL, No. 3, pp. 217-310

134 Intracranial Murmurs; Sixty-Six Cases. (Om kraniella blåsljud.) H. Koster.
135 *Chronic Polycythemia; Nineteen Cases. I. Hedenius.

135. **Chronic Polycythemia.**—Hedenius has encountered nine cases of polycythemia with pronounced pathologic conditions and also ten cases in which the condition otherwise seemed practically physiologic. He reviews the literature on polycythemia and gives the details of his nineteen cases. The high blood-pressure seems to be a complication and not a consequence of the polycythemia. In three cases the spleen became reduced in size during menstruation and the number of reds diminished. At other times they ranged from 6.1 to 14.5 millions in the first group and from 5.5 to 7.3 millions in the others. In five in the first group the figure was over 9 millions. All had different combinations of the typical symptoms, cyanosis, enlargement of the spleen and high blood-pressure, with the unusual numbers of reds. There was also a tendency to headache, slight dizziness, partial incapacity for work and restless sleep or somnolency, suggesting a cerebral-neurasthenic state. The hemoglobin percentage is relatively low so the hemoglobin index is low but the blood-producing organs show signs of exaggerated functioning. The proportion of mononuclears was also abnormally high. The low index explains why the polycythemia escapes recognition so long in so many cases. The course and nature of the chronic polycythemia seem to stamp it as a constitutional affection like gout, obesity and diabetes, and it is noteworthy that the gouty tendency was pronounced in eight of his nineteen cases. It is possible that epinephrin may have something to do with the exaggerated functioning of the bone marrow. Food poor in purins and iron seems to have a beneficial action on the subjective symptoms. Repeated venesection has given temporary relief in some cases. Roentgen exposures seem to reduce the number of reds for a brief period but exposures of the spleen have been known to aggravate the trouble. One case has been reported in which benzol was given for ten days in a daily dose of 1.5 gm. and both the subjective and objective symptoms grew worse under it. In this case, however, there were complicating pulmonary tuberculosis and nephritis. It is possible that benzol in certain cases may prove useful; a number of experiences confirming this possibility have been published. All other drugs used to date have proved disappointing. McLester gave benzol in one case for six months and the reds gradually subsided from 8,300,000 to 4,300,000. His dose was 3 gm. a day.

THE LIMITATIONS AND POSSIBILITIES OF PRENATAL CARE

BASED ON THE STUDY OF 705 FETAL DEATHS OCCURRING IN 10,000 CONSECUTIVE ADMISSIONS TO THE OBSTETRICAL DEPARTMENT OF THE JOHNS HOPKINS HOSPITAL [*]

J. WHITRIDGE WILLIAMS
Professor of Obstetrics, Johns Hopkins University
BALTIMORE

My first duty on this occasion is to express my sincere appreciation of the honor of being elected to the presidency of this association, and, as the incumbent of that office, to thank the very efficient local committee of arrangements for their efforts in making it possible to hold our meeting at a time when our sympathies are enlisted in a much broader and more serious cause.

Before taking up the discussion of the subject which I have chosen for my address, I wish to go on record as endorsing the objects of the association, as well as to bear witness to the wisdom displayed in its original organization. In no other way, I believe, could such wide-spread interest have been aroused and so much good have been accomplished as by bringing together all classes of persons interested in the welfare of infants. At each of the meetings which I have attended I have been greatly impressed with the character of the audiences, and I feel sure that the association of trained nurses, social workers, statisticians and physicians, with philanthropically inclined laymen, has been productive of an amount of good which could have been effected in no other way, and which would have been impossible had the association been made up of any single class of persons, no matter how interested or intelligent they might be.

Naturally, my interests in the association are primarily as an obstetrician and deal with the prevention of infant mortality in the earliest periods of life and even before birth. Investigation along these lines has led me to study the character of the obstetric care which is available for the great majority of women in this country, and has convinced me that it is inexcusably poor. This, however, is neither the time nor the place to consider such problems; but, when I face an audience such as this, I almost wish, were the country not already oversupplied with societies, that a somewhat similar association might be organized for the study of the problems connected with motherhood and the diseases peculiar to women, and for teaching the women of this country that they have a right to the best available treatment and care, which should be at least as good as that available for their young children, and better than that so freely given to the domestic animals by our national and state governments.

The theme which I have chosen for my address is "The Limitations and Possibilities of Prenatal Care." Certain phases of the subject have frequently been presented to you, and will be one of the topics for discussion at this meeting. I am, however, inclined to feel that it is often considered from too narrow a point of view, and my chief object in preparing this address is the hope that I may be able to impress on you that prenatal care covers a very wide field, which, while primarily obstetric, is not limited to any one branch of medicine or social activity.

The foundation of my remarks is the study of 705 fetal deaths which occurred in ten thousand consecutive admissions to the Obstetrical Department of the Johns Hopkins Hospital, 6,500 indoor and 3,500 outdoor cases. In this series I have included all deaths occurring in children born between the seventh month of pregnancy, the so-called period of viability, and full term, as well as those occurring within the first two weeks after delivery. For convenience in consideration I have classified the children as premature or mature, according as their weight varied between 1,500 and 2,500 gm., or exceeded the latter figure. Of the 705 deaths, 334 were in the former, and 371 in the latter category.

These figures somewhat underrepresent the total mortality, as they do not include many children which perished later from the causes enumerated below, either in my service, in other departments of the hospital or in their own homes. Furthermore, it must be borne in mind that they do not necessarily represent the results which may be obtained in private practice, but are based on the material entering a large general hospital, which includes many women who had been improperly treated at home and were admitted to the hospital in desperate straits.

Moreover, our material differs from that of many institutions in that 4,600 out of the 10,000 mothers were colored, thereby making it possible to compare the incidence of certain causes of death in the two races. In addition, our statistics are of unusual value for two reasons: First, that every one of the 10,000 after-births in the series has been carefully described and subjected to routine microscopic examination — a procedure which sometimes yields most important information; and secondly, that most of the dead babies have been subjected to autopsy. Consequently, the causes of death have been ascertained with more than usual accuracy; but even in such favorable circumstances, it is not always possible to make a positive diagnosis.

---

[*] Presidential address, delivered before the American Association for Study and Prevention of Infant Mortality, Boston, Nov. 12, 1914.

Table 1 gives the gross results of our investigations, the causes of death being classified into twelve general groups, while information is also given as to the prematurity or maturity of the children and their race.

The most striking features of the investigation are the following:

(*a*) Syphilis is far and away the most common etiologic factor concerned in the production of death, presenting an incidence of 26.4 per cent.

(*b*) Toxemia, including eclampsia, nephritis and occasional rare conditions, which is usually regarded as the condition *par excellence* which can be influenced by prenatal care, is the cause of only 6.5 per cent. of the deaths, and consequently is accountable for only one-fourth as many as syphilis.

(*c*) Notwithstanding most painstaking investigation, the cause of death could not be satisfactorily explained in 127 cases, or 18 per cent.

TABLE 1.—CAUSATION OF 705 FETAL DEATHS

Cause	White	Black	Total	Percentage Incidence	Premature		Mature		Estimated Percentage after Prenatal Care
					White	Black	White	Black

	705				334		371		
					705				

(*d*) The death rate is nearly twice as high in the blacks as in the whites, 9.4 and 5.1 per cent., respectively, and equals or exceeds that of the whites in all but three categories, namely, toxemia, deformities and placenta praevia.

CAUSES OF FETAL DEATH

After these preliminary remarks, I shall consider each cause of death separately, and afterward draw certain conclusions as to their bearing on the problems of prenatal care.

1. *Syphilis.*—Although it has long been known that this disease plays an important part in the causation of fetal death and should always be borne in mind when successive pregnancies end in the birth of dead children, I was greatly surprised to find that it was accountable for 186 of the 705 deaths, or 26.4 per cent., and that it constituted the most common single etiologic factor concerned. It was observed much more frequently in the blacks than in the whites, the incidence being 35 and 14 per cent., respectively, and was the direct cause of two-fifths of the deaths occurring in the premature children.

These startling figures, however, do not tell the whole story of the ravages of the disease, as routine microscopic study of the placenta showed that 350 syphilitic children had been born of the 10,000 women under consideration. In Table 1, 186 are included, leaving nearly as many more — 164 — which were still alive at the end of two weeks, and either soon died or presented manifestations of hereditary syphilis later in life. Even these figures probably underestimate the incidence of the disease, as a diagnosis was made only when characteristic microscopic changes were present in the placenta, a positive Wassermann reaction demonstrated in the fetal blood, or specific lesions were found at autopsy. Accordingly, it is probable that a certain number of cases escaped detection, and plausibility is lent to such a contention by the fact that fifty-three of the children in the next group were born in a macerated condition, and experience teaches that 80 per cent. of such children are syphilitic.

However that may be, the fact remains, which cannot be too strongly impressed on you, that syphilis is the most common single cause of fetal death, not to speak of its ravages in the children which do not immediately succumb to it, and that in the future no statistics bearing on prenatal care can make any claim to completeness which do not take it into consideration.

2. *Unknown Causes of Death.*—Strange to say, the second largest contingent of fetal deaths is included under this category. One hundred and twenty-seven children, 18 per cent., were born dead or succumbed during the two weeks following birth without our being able to discover a satisfactory explanation for the fatal issue. Indeed, the only suggestive finding was the fact that fifty-three, or nearly one-half, of the children were macerated when born. I have already suggested the possibility that undetected syphilis may have been concerned, and I believe it is reasonable to assume that probably forty of these children, or approximately one-third of the group, really perished from it. With this exception, no definite statement can be made, and we are compelled to confess that the means at present at our disposal do not always enable us to adduce a satisfactory explanation for a considerable number of fetal deaths.

3. *Dystocia.* — Under this caption I have grouped together the deaths following mechanically difficult labor, whether operative or spontaneous. In many instances it was the result of disproportion between

the size of the child and the pelvis of the mother, while in a smaller proportion it was due to abnormal presentations of the child or to other factors resulting in delayed labor. The group, however, does not include the difficult labors associated with eclampsia or complicated by hemorrhage preceding the birth of the child, which are classified under separate headings.

One hundred and twenty-four fetal deaths are included in this category, an incidence of 17.4 per cent., and occurred more frequently in whites than in blacks — 22 and 14.5 per cent., respectively. This is a somewhat surprising conclusion when it is recalled that abnormal pelves are noticed three or four times more frequently in black than in white women, and that the most extreme degrees of deformity occur almost exclusively in the former. To my mind, the explanation for this apparent contradiction is afforded by two factors: First, colored children as a rule are smaller and have softer heads than white children, with the result that moderate degrees of pelvic contraction are frequently compensated for, so that easy spontaneous labor may take place in spite of the contracted pelvis. Secondly, extreme disproportion is readily recognized, when the patients are promptly subjected to cesarean section or other radical mode of delivery, with ideal results for both mother and child. On the other hand, in white women, who as a rule present only moderate degrees of pelvic contraction, the children are comparatively large, so that the resulting disproportion is relatively great. Unfortunately, the recognition of this type of dystocia requires great diagnostic skill, and frequently is impossible until the woman has advanced so far in labor that the time has passed for the employment of the ideal method of delivery, and the child succumbs to the makeshift procedure which we are compelled to employ.

Consequently, one of the most important lessons to be learned from this group of cases is that moderate degrees of pelvic contraction are much more serious in white than in black women, and that the most expert skill is required for the recognition of the disproportion and for the choice of the ideal method of delivery.

I have carefully studied the history of each patient in this group in the attempt to ascertain to what extent the fetal mortality might have been diminished or prevented. In the first place, I found that in twenty-five cases outside physicians or midwives had failed to effect delivery and had transferred the patient to the service when the child was already dead or so damaged that it succumbed shortly after birth. Most of these deaths should be attributed to ignorance, and could have been prevented had the patients received skilled care at the proper time. On the other hand, I found an equal number of cases in which the death of the child was due to errors of judgment by myself or my assistants. In a certain proportion of the cases the result must be regarded as "the premium paid to experience," and was due to inexperience on the part of my resident, who either delayed too long before interfering, interfered too soon, or failed to select the ideal procedure for delivery. In other cases the fault was my own. In most instances, however, the error of judgment was unavoidable, and was recognized as such only after the treatment of the patient had been cooly reviewed months or years afterward. Consequently, only a certain proportion of such deaths are really preventable.

On the other hand, in seventy-four cases of the series most rigorous criticism fails to reveal any cause for reproach, and I believe that the deaths were unavoidable when all the factors concerned are taken into consideration. Thus, it would appear that a considerable fetal mortality is inherent to the class of cases under consideration and cannot be avoided.

4. *Various Causes.*—Under this heading are included seventy-nine deaths, 11.2 per cent., due to thirty different accidental complications which were equally divided between the two races. An idea as to their great variability may be gained from Table 2, which includes all conditions which were observed in two or more instances.

TABLE 2.—VARIOUS CAUSES OF DEATH

Cause	No. of Cases
Hemorrhagic diseases	14
Bronchopneumonia	13
Cord infection	6
Strangulation by loops of cord	5
Umbilical hemorrhage	4
Hydramnios	4
Enteritis	4
Gastritis	2
Asphyxia	2
Neglect	2
Cerebral hemorrhage (spontaneous labor)	2
Status lymphaticus	2
Trauma	2
Various conditions, each of which occurred but once	17
Total	79

In other words, fifty of the deaths were due to the seven causes mentioned first, while the remaining twenty-nine were attributable to twenty-three different causes. In general, very few of these deaths could have been prevented, and it is interesting to note that practically one-third were due to hemorrhagic disease or to bronchopneumonia. Furthermore, it should be observed that twelve out of the fourteen cases of the former occurred in negro children, while the incidence of the latter was identical in the two races.

I am unable to state whether or not the remarkable predominance of blacks perishing from hemorrhagic disease has any especial significance, as we are almost completely ignorant concerning its cause.

5. *Prematurity.*—Under this heading I have grouped together fifty deaths occurring in premature children which were born alive but perished during the first week of life, and whose death could not be attributed to syphilis, toxemia or any of the causes enumerated in the table. Autopsy usually revealed no definite cause for the fatal issue, which apparently was due to the inability of the poorly developed child to lead an extra-uterine life.

Cases of this character occurred much more frequently among the blacks, and are attributable in part at least to the lack of care and intelligence which so frequently characterizes that race.

6. *Toxemia.*—The various toxemic conditions were responsible for forty-six deaths, 6.5 per cent., which were equally divided between premature and mature children. Strange to say, white children were involved nearly three times more frequently than black, although it is impossible to adduce a satisfactory explanation for the difference.

The prevention of the development of these conditions is one of the chief aims of prenatal care, and it must be said that the great majority of our cases occurred in women whose pregnancies had not been supervised, but who were seriously ill before entering the service.

7. *Deformities.*—Under this heading are grouped together twenty-four deaths occurring in children which presented congenital deformities which were incompatible with life, or which gave rise to such mechanical obstruction as to lead to their death at the time of labor.

Table 3 gives an idea of their character and incidence.

TABLE 3.—DEATHS FROM CONGENITAL DEFORMITY

Deformity	No. of Cases
Acrania	6
Hydrocephalus	6
Imperforate anus	3
Congenital edema	2
Osteogenesis imperfecta	2
Hemimelus	1
Congenital cystic kidney	1
Achondroplasia	1
Spina bifida	1
Absence of pylorus, situs transversus	1
Total	24

Such deformities are attributable to errors in development occurring within the first few weeks of life following conception, and cannot be prevented. It is interesting to note that three-fourths of them occurred in white children, and were about equally divided between those which were born prematurely and at full term.

8. *Inanition.*—In this category I have collected twenty-three deaths occurring between the seventh and fourteenth days. for which autopsy failed to reveal a satisfactory explanation. As all but four of the children were premature, this group of deaths might have been considered under prematurity, the only point of difference being that death occurred during the second instead of the first week.

9. *Placenta Praevia.*—Under this heading are included twenty-two deaths which were associated with abnormal implantation of the placenta. This condition gives rise to severe hemorrhage, which necessitates the termination of pregnancy, no matter to what period it may have advanced, and is always associated with a high fetal mortality. The children were almost equally divided between premature and mature, but the most interesting feature connected with this group is that only two deaths occurred in colored children. I am unable to advance an explanation for this peculiarity, as *a priori* the condition should occur with equal frequency, and should be attended by approximately the same mortality in the two races.

10. *Premature Separation of the Placenta.*—The partial or complete separation of the normally implanted placenta before the onset of labor constitutes one of the most serious complications of pregnancy, and if complete always leads to the death of the child and frequently to that of the mother. It was responsible for thirteen deaths in our series, which were approximately equally divided between the two races.

11 and 12. *Suffocation and Debility.*—The conditions comprising these two groups occur so infrequently as not to require especial consideration.

EFFECT OF PRENATAL CARE

Having thus reviewed the various causes of fetal death in our series, I shall briefly consider each group from the point of view of prenatal care, and determine as far as possible to what extent its intelligent application might have been effective in reducing early infantile mortality. I am well aware that any such estimate is dependent on the personal attitude of the person making it, and at best can be only approximate. Definite statements cannot be made until numerous series of thousands of cases each have been adduced, in which all of the mothers had been the recipients of intelligent prenatal care. Such statistics are not yet available, and I fear that some time will elapse before they are.

1. *Syphilis.*—I feel that the chief value of this investigation consists in the demonstration that syphilis is the most important single factor concerned in the production of fetal death, certainly when the material includes considerable numbers of negro patients. For this reason it must receive important consideration from those interested in prenatal care and in the reduction of infantile mortality. Unfortunately, it is not an easy task to combat its effects. Mere education in sexual matters will do but little good in the class of patients concerned, as we are dealing with realities and not with utopian theories. What is necessary is to recognize the disease in the mother at the earliest possible moment, and then to subject her to appropriate antisyphilitic treatment in the belief that the drug administered to her will be transmitted to the child and effect its cure.

The treatment is comparatively simple, but the difficulty lies in making the diagnosis. Unfortunately, for our purpose, not more than one-fourth of syphilitic pregnant women present lesions from which a clinical diagnosis can be made, with the result that in three-fourths of the cases the condition is usually unsuspected until a dead-born child is subjected to autopsy, or a living child develops symptoms of hereditary syphilis. Indeed, in a large proportion of our cases the condition would have escaped detection had it not been our custom to examine every placenta microscopically, and to insist on an autopsy wherever feasible.

How can the desired end be effected? I am afraid that ideal results cannot be obtained unless a Wassermann test is made in the early months of pregnancy on every woman applying for obstetric aid. Such a procedure is out of the question on account of its expense, and the best that we can do is to bear the possibility of syphilis constantly in mind, and to teach those engaged in practical work to be always on the lookout for it. This would result in the detection of about one-fourth of the cases, while the other three-fourths would escape.

Fortunately for our problem, the effects of unrecognized maternal syphilis are not limited to the birth of a single dead child or by the development of a single case of hereditary syphilis, but the woman continues to give birth to a succession of dead-born children. Consequently, we should always regard the birth of a dead child with suspicion, and, unless it is perfectly apparent from the history that syphilis was not concerned, the blood should be subjected to the Wassermann test, and in case a positive reaction is obtained the mother should be given appropriate treatment, with the certainty that one-half of the children which are now lost would be saved, and the woman herself put in condition to bear normal children in the future.

This is not the time or the place to enter into a discussion as to the possibility of the paternal transmission of syphilis or the proper treatment of the disease; but enough has been said to demonstrate that ideal prenatal care demands much more than the examination of the urine and instruction as to the desirability of breast feeding, and must include an extensive knowledge of syphilis. For it is only by its recognition and treatment that this important cause of fetal death can be partially eliminated.

2. *Unknown Causes.*—In view of the fact that our knowledge at present is insufficient to permit us to determine the cause of death in this class of cases, nothing can be said of the prospect of immediate improvement by means of prenatal care, except in so far as the detection and treatment of obscure cases of syphilis is concerned. Naturally, future investigations will gradually lead to a decrease in the size of this group, and will open up avenues of prevention which do not now exist.

3. *Dystocia.*—In this group of cases the intelligent application of prenatal care in its broadest sense offers great promise of better results. As has already been indicated, the disasters in this group are in great part due to pelvic abnormalities, or to excessive size or abnormal presentation of the child. Such conditions cannot be detected or remedied by the most intelligent prenatal nurse, and their recognition will be possible only after all women have been educated to go to a competent obstetrician or to a well-regulated obstetric dispensary for a preliminary examination one month before the expected date of confinement.

If abnormalities are found, the woman should enter a hospital for delivery, and the public should be taught to realize that safety is to be found only in ideally organized obstetric hospitals. Too many sins of omission and commission are now covered by the hospital roof, and in many the sense of security is illusory, as the woman may be treated by short-term assistants, who are often less competent than the much-maligned practitioner. These women should not be delivered in their own homes by a doctor or midwife, or even by the outdoor service of the hospital, as their safety and that of their babies depend on the expert service which can be obtained only in a well-regulated hospital. Generally speaking, even in the absence of a recognized abnormality, the history of a dead-born child in a previous labor should always be regarded as an indication for hospital treatment.

It is my belief that at least two-thirds of the fetal deaths due to these factors could be prevented if suitable care were available. On the other hand, greater optimism is not permissible, as, no matter how skilled the medical attention may be, a considerable mortality will always be associated with such cases.

4. *Various Causes.*—As was indicated in the corresponding previous section, the deaths occurring in this group are due to a large number of accidental factors, concerning whose cause and prevention we are in great part ignorant. Consequently, it is not probable that any great diminution can be effected in this group by the means at present available.

5. *Prematurity.*—Prenatal care and instruction offer great possibilities for the diminution in the number of deaths due to this cause. In her visits to the homes of ignorant and overworked women the prenatal nurse can prevent many premature labors by giving instruction in personal hygiene, insisting on rest and abstention from excessive work during the later months of pregnancy, and, where imperfect nutrition is manifest, by putting the woman in touch with appropriate agencies for relief.

It has been established beyond peradventure that one of the most potent causes of premature labor and the birth of poorly developed children consists in overwork and poor nutrition in the last months of pregnancy; and my own observation has demonstrated that the smaller size of the average colored child is dependent on insufficient and unsuitable food, and that a stay of several weeks in the hospital before labor will result in an increase of from 8 to 16 ounces in the size of the children which will then compare favorably with those of white women in comfortable circumstances.

While the state is not yet prepared to follow the example of France and Germany in ensuring the working woman a period of rest during the weeks immediately preceding labor, I am confident that intelligent prenatal care along the lines indicated would soon do away with at least one-half of the deaths due to prematurity.

6. *Toxemia.*—The fact that only forty-six children in our series perished as the result of toxemia indicates that preventive work in our service has resulted in appreciable improvement, as the great majority of deaths occurred in the children of women who had applied for aid only after the disease had become fully established.

For some years the prevention of toxemic conditions has been recognized as one of the main functions of prenatal care and has accomplished great good. Every practitioner knows how difficult it is to induce even intelligent women to send specimens of urine for examination at regular intervals, and that it is practically impossible in the type of women who come to the obstetric dispensary. Consequently, one of the most important functions of the prenatal nurse is to follow up the patients in this regard, and when abnormalities are detected to see that the women enter the hospital for prophylactic or curative treatment.

In my own material I am confident that the mortality from this cause could have been reduced four-fifths had suitable prenatal care been available. At the same time, I think it right to insist that complete abolition of death from this cause is an unattainable dream, as I know from my own experience that patients who have been constantly under ideal supervision occasionally develop and sometimes die from toxemia.

7. *Deformities.*—Under the appropriate heading I indicated that the deformities in question originated during the first weeks of pregnancy, and therefore no diminution in the number of deaths from this cause can be expected from prenatal care. Furthermore, I am inclined to believe that more careful investigation will lead to the recognition of an increasing number of such cases, as is shown by the fact that since completing the tabulations on which this study is based, I have seen two dead babies born which would previously have been classified in the "unknown cause" group, but in which very thorough autopsy demonstrated that death had been due to abnormalities of the nervous system which were incompatible with life and which had originated during the first weeks of development.

8. *Inanition.*—All that can be said of the prevention of death from this cause has already been said under the heading "prematurity."

9. *Placenta Praevia.*—Only a few of the twenty-two deaths from this cause could have been prevented by prenatal care and then only indirectly. Had all of

the women suffering from this abnormality been taught that bleeding during the last months of pregnancy was a serious matter and demanded expert hospital care, it is probable that a considerable number of them and their children might have been saved, instead of being sent to the hospital in a dying condition by doctors or midwives who had attempted to treat them in their own homes.

The greatest hope for improvement in this condition lies in preventive measures, put in operation months or years before the condition develops. In other words, since the causative factor in the production of placenta praevia consists in inflammatory conditions of the lining membrane of the uterus, resulting from infection in previous labors or abortions, the chief means of prevention consists in good obstetric care in preceding labors.

10. *Premature Separation of the Placenta.*—Thirteen fetal deaths were attributable to this cause, but as we are in great part ignorant of the exact mode of production of the accident, it is evident that even the most intelligent prenatal care could not have been effectual in preventing it.

Furthermore, in view of the fact that the complication runs a rapid course and is frequently very difficult of recognition, it is unlikely that the majority of women affected could have been sent to the hospital sufficiently early to have been subjected with any great hope of success to the radical operative procedures which are essential for saving the child; while in many instances it is a matter of congratulation if it is possible even to save the mother.

11 and 12. *Suffocation and Debility.*—These factors in the causation of infantile death occurred so rarely in our series of cases and were so clearly beyond the influence of prenatal care that they do not call for consideration.

Having thus reviewed the causes of fetal death in our series and considered the extent to which they might be decreased by ideal prenatal care, I have indicated in the last column of Table 1 what appears to me to be the proportion of deaths which must be expected and which cannot be appreciably diminished by any means at our disposal.

It would therefore appear that the fetal mortality in our material might have been reduced 40 per cent. had it been possible for all of our patients to have the advantages of the type of prenatal care which I shall briefly sketch, and with the further proviso that they had received practically ideal obstetric care in the hospital. In this event nearly 300 additional children could have been discharged from the service in good condition.

In criticizing our results, it should be borne in mind that our material is of the type which ordinarily applies for aid at a large general hospital, and is less favorable than in many institutions for the reason that nearly one-half of the patients are negroes with scant intelligence and afflicted by contracted pelves and syphilis to an extent in no way approached by white patients. In general, I believe I can fairly assert that the treatment at the time of labor compares favorably with that of other institutions, but on the other hand, I must frankly confess that the care during pregnancy was far from ideal, and until two years ago consisted solely in such supervision as could be afforded in the dispensary to patients who voluntarily obeyed our directions to return at stated intervals for supervision and examination. During the past two years, however, thanks to the cooperation of the "milk fund" nurses and of the children's clinic, conditions have materially improved, and at the present moment the hospital has provided funds to enable us to make a start with efficient prenatal care.

If we have to register a total mortality of 7 per cent., with all the resources of a large hospital and university behind our service, which has been fortunate in being provided with an exceptionally competent nursing and resident staff, it is appalling to contemplate the conditions which must obtain in private practice among the poor and in some institutions which are less favorably situated.

I shall now outline briefly my ideas concerning efficient prenatal care in large cities, and shall consider its relations to other departments of medical and social service work.

I believe that too narrow a view is ordinarily taken of the scope of prenatal care, which is regarded on the one hand almost solely as a means of preventing toxemia, and on the other as a side issue in the propaganda for breast feeding. If ideal results are to be obtained, neither view is correct, and if the consideration of the facts which I have presented has served its purpose it will have convinced you that broad-minded prenatal care has an immense scope and can be carried out effectively only under the auspices of a well-regulated obstetric department which can command the enthusiastic cooperation of carefully trained obstetricians, social service workers and prenatal and outdoor obstetric nurses, and at the same time is in close affiliation with a children's clinic with its corps of organized workers, or at least with a well-conducted milk association. Furthermore, the closest relations must be maintained with the other department of a general hospital, whose resources should be readily available to the mother and children when necessary.

ORGANIZATION OF PRENATAL WORK

In an obstetric department such as I have indicated, the prenatal work should be conducted primarily from the dispensary, which should serve as the portal of entry for all prospective patients irrespective of whether they expect to be treated in the hospital or in their own homes.

The first requisite for such a dispensary is that it should have proper quarters, an ideal personnel and adequate financial support. The purely medical work should be under the direct supervision of the director of the hospital, and should be carried out by medical men who are sufficiently well trained to make a reliable diagnosis. A considerable proportion of them, at least, should be assistants living in the hospital, in order that the work of the indoor and outdoor departments may be satisfactorily coordinated. In addition to the medical assistants, the necessary number of nurses should be in attendance to care for the ordinary needs of the patients, but more important is the requisite number of prenatal nurses. These should be graduate nurses with considerable obstetric experience, who have also had a certain amount of training in social service work, and should receive adequate salaries.

Patients should be encouraged to come to the dispensary as early as possible in pregnancy. After registration, a careful physical examination should be made and its results recorded. This should not be limited to purely obstetric conditions, but should include the entire body, with especial reference to syphilis and tuberculosis, and the condition of the kidneys. At this visit blood should be withdrawn for a Wassermann test, should anything in the physical examination or the previous history of the patient indicate its necessity.

If everything is apparently normal, and the patient desires it, she should be tentatively registered as an outdoor patient, to be eventually delivered in her own home; otherwise, she should be registered as a prospective hospital patient.

In either event she should be instructed to report to the dispensary at stated intervals as long as she remains well, and to bring a specimen of urine at each visit. She should also be given a card containing concise directions concerning the hygiene of pregnancy. and mentioning the important untoward symptoms which might supervene. Should such be noted she should report at once.

At the first visit to the dispensary, the prenatal nurse should arrange to call on the patient at her own home within the week. At this visit she should make a social survey of the surroundings, and determine whether the patient is a proper object for charitable care. If the surroundings are not suitable, the patient should be persuaded to enter the hospital for delivery. The nurse should also amplify the printed directions concerning the hygiene of pregnancy, and impress the woman with the necessity of suckling her baby.

After this initial visit, an important part of the duties of the nurse is to keep track of the patient by means of a card index, and in case she does not return to the dispensary within one week of the appointed time, to visit her again in order to ascertain why she failed to keep the engagement.

Every patient should return to the dispensary for a final examination one month before the expected date of confinement, and the decision as to whether she is to be delivered in the hospital or in her own home will in great part depend on the findings at that time. In the latter event she should be visited again by the prenatal nurse in order to ascertain whether the necessary arrangements have been made for the approaching confinement. Ordinarily, further visits will not be necessary until after the child is born, but a visit should be made just after the student and postpartum nurse cease their visits. This is necessary partly to check up the work of the outdoor service, but principally to put the patient and her baby in touch with the children's clinic with instructions to take the baby to it should necessity arise, and on returning to the hospital the nurse should register the child at the children's clinic or with the "milk fund" nurse so that it can be followed up by the proper agencies.

In the case of patients entering the hospital for delivery, the prenatal nurse's work usually ceases with the visit made one month before delivery, as the subsequent supervision will devolve on the nursing staff of the hospital. On the day before the discharge, the mother and baby should be taken to the children's clinic for registration, so that the baby may be under its supervision for the next year.

Prenatal care does not necessarily end here, as it has to take thought of what may happen in future pregnancies, as well as of the preservation of the general health of the mother. Consequently, when the existence of syphilis is not discovered until after the birth of the child, a mechanism should be developed which will ensure proper treatment, either under the auspices of the obstetric service or in some special department of the hospital. To bring this about without unnecessarily going into details concerning the disease will often require great tact, and will tax the resources of many nurses. Furthermore, when patients are discharged with conditions ultimately requiring operative treatment, but which could not be undertaken during their stay in the lying-in ward, an attempt should be made to see that they ultimately return to the obstetric department or to some other department of the hospital for the necessary operation, both for their own sake and for that of their unborn children.

CONCLUSION

I hope that by this brief outline and by my figures I have been able to make clear how complicated prenatal care is and how inextricably it is connected with the work of the obstetric hospital. It is not merely a matter of a few visits by a nurse to the patient in her own home, but should consist in the coordination of the medical, nursing and social service resources of the hospital in the effort to obtain such treatment and supervision for the mother as will offer the greatest possible guarantee for the safe delivery of a normal child, which can be kept healthy by maternal nursing.

VALUE OF HYDROTHERAPY IN UROLOGY *

W. F. MARTIN, M.D.
Urologist to Battle Creek Sanitarium
BATTLE CREEK, MICH.

The object of this paper is to call attention to the valuable therapeutic effects which can be secured by a more general and systematic use of hydriatic procedures. It is no new remedy. Hydrotherapy, both internal and external, has been known and employed throughout the ages, but it does not occupy that large sphere of usefulness which its merits justify, because its advantages are not fully appreciated.

Historically we find records of its use in the early literature of Assyria, Egypt and China. It was extensively developed and used by the Greeks and Romans, who originated the hot air and vapor baths. Hippocrates' writings revealed his quite perfect knowledge of the therapeutic action of certain hot and cold applications. His explanation of their physiologic action is strong testimony to his great wisdom, for it agrees in the main with the facts which we hold to-day, that have been established by extensive experimentation.

In every age certain men, as Asclepiad, Kneipp, Pliny, Presnitz and others, have arisen in different places, extolling the great advantage of water as a remedial agent. Empiric as their knowledge must have been, they added their part to our present system, which has been so well established on a rational and scientific basis by the hard work of many scientific men.

Recent studies in immunity have taught us the wonderful inherent power of the blood and blood-

---

forming organs in combating infections, and have demonstrated the actual warfare which takes place between the forces of the host and those of the invader. Victory for the host is effected because of the supremacy of its forces over those of the invader. The purpose of any therapeutic remedy should be to assist Nature in her combat by facilitating the circulation and the mobilization of her forces. To be of the greatest value a remedy must not only be directed toward the relief of the symptoms, as pain, but it must at the same time arouse and aid Nature's forces to remove the cause. To accomplish this there is no agent more effective, and whose actions can be more definitely directed, than well-established hydriatic procedures. Not only the amount of blood going to any organ can be definitely increased or diminished, as may be desired, but its character can be improved and altered by the different applications. It is the most potent therapeutic agent known to stimulate the active forces of blood and circulation, proper applications increasing the blood-cells, stimulating their activity, and increasing the blood alkalinity.

Before discussing specific applications it will be valuable to consider a few of the salient principles involved in the action of water on the system, which can be best reviewed by studying: (1) the effects of cold, (2) the effects of heat, and (3) the mechanical or reflex effects.

EFFECTS OF COLD

The primary or intrinsic effect of cold is that of a vital depressant. This is well illustrated by conditions accompanying prolonged exposure to cold. There is slowing of pulse and respirations; the nerves become benumbed; body temperature lowered; and glandular secretions diminished. The degree of effect produced depends on the temperature and duration of exposure. The immediate effect of cold is the depression of activities of the structures in direct contact. The vessels of the skin are contracted, and the blood driven into the larger internal vessels, producing a local anemia and internal hyperemia. If the exposure is of short duration there is a reaction with opposite effects. The skin now glows, and becomes warm. There is a tonic dilatation of surface vessels with resulting hyperemia; increased pulse and respiratory rate, rise of temperature, and stimulated secretions. This phenomenon is due to the reaction or secondary effect of cold which is tonic in nature.

If the exposure to cold is prolonged its depressive effects become more pronounced, and the contraction of surface vessels and the general depression continue. Excessive blood is forced into the deeper organs, as kidneys and other glands, except those of muscular structure. (The contractions of the muscle fibers decrease the size of these organs, and cause an expulsion of their congested blood.) The sensory nerves being subjected to the prolonged exposure of the powerful thermic impulses produced by the cold become exhausted, and the pronounced reaction which follows the short application is not produced, and the primary effect of the cold continues following the application, sometimes for two or more hours.

Effects on Blood.—The effect of cold on the blood is striking. Winternitz reports an increase of 1,860,000 cells after an application of cold. White corpuscles increased up to 300 per cent. Kellogg[1] demonstrated temporary increase of 500,000 red cells, 5,200 white cells and 3 per cent. hemoglobin, following a hot and cold application. Baruch's experiments showed an increase of 1 to 2 per cent. following cold sprays and other applications. Henocque showed that hot and cold applications increased the rate of reduction of oxyhemoglobin. Strasser showed that general cold applications increased the blood alkalinity, increased the amount of urea, uric acid, ammonia, earthy phosphates, and xanthin bases, which demonstrates the powerful stimulating tonic effects of short cold applications. Fleury demonstrated with his experiments with belladonna that intestinal absorption was greatly accelerated by cold application. Short applications of cold increase heat elimination by the reaction following it, favoring perspiration. Prolonged and very cold applications produce congestion of the kidneys, which may continue even to the extent of producing albuminuria. *Cool* (not prolonged very cold) baths decidedly increase the amount and density of urine eliminated. The toxicity of the urine in fever cases, treated by cool baths, has been demonstrated to be increased sixfold. Cold lowers both surface and internal temperature. Fleury records a lowering of body temperature 7 degrees by cold baths. There is a greater change in fever than in normal cases, and it is greatly enhanced by friction. Cold lowers temperature by direct absorption of heat. Prolonged cold applications lessen the power of reaction by exhausting the sensory nerves, and lessen the heat production by exhausting the heat producing centers, so that the temperature may remain lowered for several hours before the body can react and be returned to normal.

PHYSIOLOGIC EFFECT OF HEAT

Heat is a vital stimulant. This is well demonstrated by noticing the vivifying influences of warmth from a fire after prolonged exposure to cold. The effects of heat applied differ with the temperature, duration and mode of application. Currie says that the first effect of moderate heat is to produce a local hyperemia of the tissues by stimulating the vasodilators. While moderate heat relaxes the surface vessels, very hot applications cause a primary contraction of the vessels in the skin. With applications of short duration the vasoconstriction is soon replaced by a vasodilatation and there is a temporary contraction of the internal vessels coincident with the contraction of surface vessels, which is soon followed by a relaxation. This relaxation of the surface vessels, permitting the blood to circulate freely in the skin, is a powerful derivative measure in relieving the congestion of deeper parts. Applications of warm water stimulate the vasodilators, while very hot applications temporarily stimulate the vasoconstrictors.

Experiments have been performed which show the marked effects which the applications of heat have on the vital organs. Winternitz showed that following a hot bath there was a decrease in the blood-cells, a greater reduction being noticed in the whites than in the reds. Strasser showed that general applications increase the acidity of the blood, by increasing the acid-phosphate content. Magiori demonstrated the muscular activity to be greatly reduced by the effect of heat. Kellogg showed that following an immersion bath of 112 degrees for twelve minutes the strength, as determined by the universal dynamometer, dropped from 6,480 pounds to 5,415 pounds, a loss of 1,065 pounds, or 16 per cent. Heat first slows, then increases the pulse, diminishes blood-pressure, increases metabolism by raising the body temperature, thus increasing the elimination of urea. Short applications of heat are nervous excitants. If this stimulating or exciting effect is prolonged it exhausts the stored nervous energy, very much as a continuous contact of the circuit of a dry cell soon exhausts it. Neutral applications are soothing, producing their sedative effects by protecting sensory nerves from external thermic stimulation.

REACTION EFFECTS

The phenomena of reaction manifestations following application of heat or cold have been carefully worked out by the experiments of Schuller, Goltz, Naumann and others, who have demonstrated it to take place directly through the nerves. Thermic stimuli producing afferent impulses are carried to the caloric centers, from which efferent impulses are modified and transmitted over the sympathetic, affecting the vasoconstrictors or vasodilators. The reaction effect is opposite from the action and is the result of the efforts of the organism to resist any external interference with the normal temperature. It is well illustrated by the change accompanying a cold bath. The direct action is to chill and blanch the skin by contracting surface vessels, slowing of pulse and respiration, and increasing blood-pressure, whereas the reaction is essentially opposite, reddening and warming of the skin vessels, increased pulse and respiratory rate and general feeling of well being. The primary effect of short heat and reaction from short cold are tonic, while the primary effect of cold and reaction from hot are atonic. The end result of any application depends on the reaction, and to be effective the treatment must be directed with this object in view, and so applied as to obtain it.

REFLEX ACTION

Another important factor in the action of hydriatic measures is reflex action. All the internal organs are reflexly connected with some external surface. This is well illustrated by the perceptible effect on the bladder of applications of cold to the hands or feet, and on the uterus by applications to the breast. These various areas have all been carefully worked out and a knowledge of them is essential in prescribing hydrotherapy. By utilizing them more decided results can be obtained by fluxion effects. For example, hot blanket packs relieve congestion in the kidneys by diverting blood into the skin. An ice bag over the lower third of the sternum, the reflex area for the kidneys, simultaneously applied, doubles the action of the pack by reflexly contracting the vessels of the kidney; thus is produced a pulling and pushing effect.

APPLICATIONS OF SPECIAL VALUE IN UROLOGY

As in every branch of medicine, our treatment must possess a twofold function, one directed to the local condition, the other to the upbuilding of the patient's general resistance. We are apt to be too reliant on our aggressive measures and not sufficiently consider the advantages of increasing the defensive powers of the body. Much can be accomplished in combating local infections by relieving congestion and producing a more active circulation of blood, richer in leukocytes. The local accumulation of toxins is prevented by their being more rapidly carried away to the glands and organs of elimination, thus preventing their inhibitory effect on the phagocytic action of the leukocytes. Frequent applications of short hot and cold, either as fomentations and cold compresses or immersions in alternate hot and cold, constitutes a valuable adjunct to any treatment in combating infections. Cases of acute specific urethritis experience relief and more speedy cure by immersing the organ in alternate hot and cold water several times a day, as an adjunct to regular treatment. Perhaps the most frequently prescribed hydriatic measure by urologists is the sitz. My experience has demonstrated to me that we do not get the results to be obtained from this very valuable measure when proper technic is not followed. The marked analgesic effect of a hot sitz is responsible for our ordering its use so frequently. Patients, when taking their own treatment, find the relief so gratifying that they remain in it too long, which results in an atonic reaction following, that is more or less debilitating to the defensive properties of the blood, and the value of the measure is thus thwarted. When used for its analgesic properties for calculus colic, this relaxed effect is desirable, but not so in combating chronic congestions or infections. The best effect is obtained from a short hot sitz, from 115 to 120 F. for five to eight minutes, followed by a short cold dip or effusion, the reaction of which prolongs the primary tonic effect of the heat, by producing a tonic dilatation of the peripheral vessels, and a more active circulation. A hot sitz should always be followed by a cold sitz when treating chronic infections. For this reason sitz tubs in hospitals and institutions should be arranged in pairs in order to facilitate taking alternate hot and cold applications. In private homes, the effect can be obtained in a measure by gradually cooling the water or dashing cold on the parts from a bucket. In cases of chronic infections, the advantage of such a bath is greatly augmented by preceding it with alternate hot and cold sprays and ascending perineal douches.

I wish particularly to emphasize the value of the prolonged cold sitz. My attention was attracted to its virtue by its extensive use among the gynecologists, who use it so effectively in the palliative treatment of uterine fibroid, with chronic congestion accompanied by menorrhagia. They have demonstrated by experience that the reaction following short cold sitz baths increases the circulation in the uterus, which aggravates the menorrhagia, but prolonged (from twenty to thirty minutes at 60 to 70 F.), produces continued contraction of the pelvic and abdominal viscera, with a relief of congestion following. The prolonged active stimulation of the vasomotors exhausts them, thus losing their power to react, so that the primary effect of the cold is continued after the bath. Much of the benefit derived by the patient from this measure is due to the contraction and tone to relaxed intestinal viscera, which noticeably increases their activity and thus stimulates nutrition and intestinal elimination. This measure has proved very valuable to me in the palliative treatment of prostatic hypertrophies with congestion, malignant growths with hemorrhages, atonic dilated bladders (especially following prostatectomies) and in sexual debility.

Care must be exercised in the beginning of its use. Weak and debilitated patients should not be given the prolonged very cold bath until their ability to react is established, which can be done by gradually from day to day reducing the temperature and extending the time. Thus "tolerance" is established. Reaction can be greatly facilitated by a simultaneous hot foot bath, and especially by vigorous friction to parts immersed. Chilling can be prevented by protection of the shoulders with flannel. The cold sitz should be preceded by a hot rectal irrigation, and followed by a spray. It is positively contra-indicated in all cases of vesical tenesmus.

The neutral sitz, taken with water at 92 to 95 F. for from fifteen to thirty minutes is very valuable, because of its soothing and sedative effect in all irritable conditions, accompanied by priapisms, erotomania, etc.

Another useful measure to me, which can be utilized by patients at home, is the heating pelvic pack. It consists of a piece of linen, flannel and mackintosh, shaped and applied like an infant's napkin. It is used as a heating compress to any other part by wringing the linen out of ice water and applying next to the skin, covered by flannel and mackintosh. Its action is that of a heating pack, producing dilatation of superficial vessels, with relief of internal congestions. It possesses a decided value in the relief of pain and for activating the circulation in cases of cystitis, prostatitis, epididymitis, etc. It is a valuable after-treatment following a sitz or hot fomentation, and is best employed at night. Its ease of application and value commends it to a more general use.

The value of the ice bag, fomentation, pyscrophore, and numerous other local measures of merit can only be mentioned.

General derivative and eliminative measures, as packs and electric light baths, and tonic measures, as hot and cold applications to the spine, salt glows and general hot and cold sprays, deserve special mention. They are valuable in stimulating general vital tone. With their proper use, weak, anemic and debilitated patients, who may be suffering from some condition demanding radical treatment, and unable to stand it, can be built up and prepared for it.

Treatments consisting of combinations of these applications, graduated as the patient's ability to react indicates, are effective in all cases of acute and chronic infections. Patients feel the boost and stimulating effect of each treatment, which gradually increases their natural offensive and defensive powers. Especially in tuberculous infections, used together with proper hygiene, vaccines, etc., suitable tonic hydriatic applications possess especial merit in raising the opsonic index, besides affording most grateful relief of painful symptoms.

Nothing can be more essential to a patient about to have an operation involving the urinary tract, than to have his blood pure and free from toxins and his skin and elimination active, to increase which no measure approaches in value suitable hydriatic applications, and I predict that the time will be when hospitals and all surgical institutions will be equipped to give surgical cases hydriatic training to put the patients in the best possible condition for operation. If more attention is given to the circulation and activity of the skin prior to operation, there will be fewer cases of renal failure following surgical procedures.

The routine use of the hip and leg pack followed by cold-mitten friction after surgical procedures is a valuable measure to abort shock and pulmonary congestions. These are conveniently given by the use of the electric thermaphore pack, which is placed on the bed and the current turned on before the patient returns from the operating room. The patient is thus put at once in a warm pack, which is folded around the legs and hips and heated by the electric current for ten or twelve minutes. A cold-mitten rub completes the treatment.

The technic of these applications is an important feature and essential to their successful results, but the extensiveness of the subject necessitates referring the reader to standard text-books on the subject. If I have succeeded in calling attention to the fact that hydrotherapy is a definite science, that elaborate indications have been developed, which are based on a sound physiologic foundation, and that it is not an empiric measure to be used in a haphazard way, I am thankful and I can assure you that time spent in becoming more acquainted with the great resources of hydrotherapy will place in your hands many useful measures in combating disease.

ABSTRACT OF DISCUSSION

Dr. D. Miller Barr, Atlantic City: I have had a large experience in this direction. In 1883 I had a patient with chronic rheumatism, a tall man, strong, energetic, but I could not control the condition. I at that time opened a sanatorium employing hydriatic appliances. In 1884 I gave this patient a Russian bath every morning and a Turkish bath every evening. In two days he threw away his cane, gained two pounds a day for two weeks, and went home well. I do not know whether you have observed that there are two batteries at work in the system. There is a faradic battery which sends impulses to the muscles and which is subject to the will. Now these muscles must be exercised in order to keep up their strength, and this battery needs rest—eight hours out of every twenty-four. The galvanic battery is that battery which commences before birth and keeps up a continuous action until death. It acts on the heart and lungs and the general organs of the system. It is not subject to the will. I believe we have a definite way of stimulating, exercising and differentiating the work of this galvanic battery, the battery which supplies the organs of the body with vitality. This weakens like any other ordinary battery at times and this method of treatment stimulates it, causes additional vibration and action, and thereby accomplishes the wonderful and desirable effects which are described in the paper.

THE PRACTICAL VALUE OF CHEMICAL TESTS OF RENAL FUNCTION IN SURGICAL CONDITIONS OF THE URINARY TRACT*

W. F. BRAASCH, M.D.

AND

G. J. THOMAS, M.D.

ROCHESTER, MINN.

The practical value of an estimation of renal function by means of chemical tests has not as yet been definitely determined. Medical literature during the past decade has been replete with articles concerning this subject. With the advent of each of the various functional tests, it was believed that the means had been discovered whereby an exact estimate of renal function was possible. In 1909 the use of phenolsulphonephthalein as a renal functional test was advanced by Rowntree and Geraghty, who asserted that in its use many of the objectionable features of other tests had been overcome. Since then many articles have appeared, largely corroborative of the assertions of

* Read before the Section on Genito-Urinary Diseases at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

Rowntree and Geraghty. As a result, the general impression now in this country is that an estimation of renal function by means of chemical tests is necessary before any surgical procedure can safely be made in the urinary tract.

In our experience phenolsulphonephthalein undoubtedly embodies many of the virtues which the various other tests lack. Since phenolsulphonephthalein is also representative of the underlying fallacies common to all functional tests, its use will be illustrative of the practical value of such tests. In an effort to determine its practical value when applied to surgical conditions of the urinary tract, we have employed it in 612 cases. In the review of these tests, they have been studied in regard to their value when applied to the following conditions: 1. For the purpose of determining the efficiency of the remaining kidney. 2. The estimation of renal functional capacity in cases of urinary obstruction. 3. As an aid to the diagnosis of doubtful lesions of the kidney.

In the literature on the subject of renal functional tests the statement is frequently made that the greatest danger in renal surgery is insufficiency of the other kidney. Rowntree, in a recent article, says, "Uremia after operation has been responsible for a large proportion of the mortality in surgical cases." This observation, however, has never been proved by an extensive survey of a large series of operated cases. Of the 485 patients on whom nephrectomy was performed at the Mayo Clinic during the past five years (June 1, 1909, to June 1, 1914), nineteen died as the result of the operation. A review of the post-mortem findings in these cases showed that renal insufficiency was the cause of death in but one case in which a complete cystoscopic examination was made prior to operation. In this patient a nephrectomy had been made for unilateral renal tuberculosis. Although the clinical symptoms prior to operation were suggestive of renal insufficiency, the operation was made for relief of acute pain referred to the affected kidney. In two other cases the remaining kidney was insufficient because of tuberculous infection. Because of difficulties in cystoscopic technic, neither of these kidneys could be catheterized. In one of these cases the combined phenolsulphonephthalein output in two hours was 38 per cent. prior to operation. A review of the necropsy data would lead us to believe that the cause of death following renal surgery will more often be the result of infections and possible errors in surgical technic than of insufficiency of the remaining kidney.

It is a well-known fact that when one kidney is diseased the functional activity of the other kidney may be temporarily reduced. The degree of reduction may be so marked as to suggest an actual lesion. The degree of functional reduction, however, is not necessarily commensurate with the extent of actual destruction of tissue. The fundamental weakness of all renal functional tests as an aid to prognosis is that while they may show the degree of functional activity at the time of examination, one cannot determine from them what the functional capacity may be when the existing pathologic conditions are corrected. It has been our experience that the fundamental surgical principles and the clinical data, including a careful cystoscopic examination, are to be relied on in determining whether or not a patient should be operated on. In other words, if a surgical condition is present in one kidney, operation is indicated provided there is a fair amount of normal urine in the catheterized specimen of the other side and that the patient does not give evidence of the well-known clinical symptoms of renal insufficiency.

URINARY OBSTRUCTION

We have employed the phenolsulphonephthalein test in 168 cases of prostatic hypertrophy. In the majority of cases the test was repeated at regular intervals in order to note the degree of comparative progress. It has been asserted that with a persistent low output of phenolsulphonephthalein in spite of treatment we have evidence of renal insufficiency which would contraindicate operation. While it would probably be impossible to set any arbitrary percentage as the operative danger line, it is generally understood that a 20 per cent. return in two hours might be so regarded. Our series includes eleven patients operated on with an output of less than 20 per cent., all of whom had repeated examinations and long-continued treatment. Of these eleven patients, but one died, evidently from cardiac rather than renal insufficiency. In two patients, even after months of treatment, the return in two hours was so slight as to be scarcely measureable and yet both made uneventful recoveries, one of whom two years afterward is reported in excellent health. On the other hand, two patients with a phenolsulphonephthalein output of 30 and 45 per cent., respectively, after treatment of the bladder died with clinical symptoms of uremia, and several patients with an output of over 40 per cent. prior to operation developed uremic symptoms after prostatectomy but finally recovered.

Two patients, with a phenolsulphonephthalein output of over 75 per cent. in two hours, died following operation. One patient died with clinical evidence of uremia and a pathologic diagnosis of nephritis, largely glomerular, in both kidneys. The other patient died with evident cardiac dilatation, and the pathologic examination of both kidneys showed a chronic parenchymatous nephritis.

It has been asserted that successive tests are necessary to establish the functional capacity and that only when the amount of dye secreted increases progressively is the efficiency of renal function established. In the ten patients operated on with an output of less than 20 per cent., the amount remained practically stationary throughout treatment. In several cases, the secretion had been around 20 per cent. after the first reaction to treatment, then rose to 30 per cent., but dropped to 20 per cent. or even less prior to operation. We have concluded that although the amount secreted usually increases after drainage and treatment of the bladder, a stationary or even decreasing output should not influence the prognosis, provided the patient's general condition is improving.

Of interest is a review of the specific gravity of the urine. While as a general rule a drop in specific gravity was accompanied by a drop in the phenolsulphonephthalein output, there was no certain degree of parallelism between the two tests. Thus of sixty-three patients in whom the phenolsulphonephthalein output was over 50 per cent., in thirty-two the specific gravity remained lower than 1.010. On the other hand, of the eleven cases with less than 20 per cent. phenolsulphonephthalein output, nine had a specific gravity of less than 1.008.

We believe, however, that the clinical evidence of renal insufficiency after the usual course of treatment is of greater importance than any functional tests, and should determine whether or not prostatectomy is indicated. That we are correct in our observation is proved by the fact that recently a series of ninety-seven prostatectomies was performed at the Mayo Clinic without a death.

Probably the greatest value of the functional test will be as an aid to the diagnosis of doubtful lesions of the kidney. For this purpose, phenolsulphonephthalein is admirably adapted. The presence of a marked diminution of dye-secretion on one side should be regarded as indicative of the existence of some pathologic lesion. Its absence, however, will not exclude the possibility of the existence of a lesion. Unfortunately, technical difficulties accompanying ureteral catheterization are frequently the cause of error in the functional estimate, and in order to corroborate the findings it may be necessary that the patient undergo repeated examinations. Slight differences in the functional output between the two kidneys are not of much practical value. To be of much diagnostic significance, the comparative difference in the functional output must be marked. The phenolsulphonephthalein test is frequently of considerable value when applied in the diagnosis of renal lithiasis, ureteral lithiasis, hydronephrosis, renal tumor, renal tuberculosis, renal infection, bilateral cystic kidney, essential hematuria and atrophic kidney.

RENAL STONE

When stone is present in a kidney, a comparative diminution in the functional output will be found in the majority of cases. It will be found in practically every case in which the stone is of considerable size and there is marked destruction of renal tissue. It will frequently happen, however, when the stone is small and when there is little or no infection, that the diminution in secretion will not be enough to be of diagnostic value. Since shadows in the roentgenogram of stones of this type particularly require identification, the practical value of the functional test as an aid to their identification will be found to be limited. The absence of any diminution of dye-secretion, therefore, will not exclude the possibility of a stone being present.

The degree of diminution of the phenolsulphonephthalein output will not be found to be commensurate with the degree of destruction of renal tissue. As a rule, the degree of diminution in functional output will be much greater than the actual destruction of tissue. Thus in several recent cases of stone in the kidney, the functional output of the affected kidney was but 1 or 2 per cent. in fifteen minutes, while in the other kidney it amounted to 10 or 15 per cent. At operation, the affected kidney was found to be practically normal. Following the removal of the stone, the renal function returned to normal. From this it must be inferred that the reflex irritation from stone will frequently be the cause of temporary diminution in renal secretion.

With bilateral nephrolithiasis, the test may be of value in determining the comparative degree of renal obstruction. If but a trace of the dye returns from one kidney, the destruction of tissue has probably progressed to such a degree that nephrectomy usually is indicated—a particularly valuable procedure when the urine is not markedly purulent. In one case, however, of bilateral nephrolithiasis, the same amount of dye was secreted from both sides. At operation, one kidney was found to be so much destroyed that nephrectomy was necessary, while the other was in comparatively good condition. If, with bilateral nephrolithiasis, but a trace of phenolsulphonephthalein is present in the combined urine two hours after injection, the advisability of operation would be questionable. Two such patients came under our observation. In one, operation was refused because of clinical evidence of renal insufficiency and toxemia. The other was operated on and was reported alive six months later.

STONE IN THE URETER

Marked diminution in phenolsulphonephthalein secretion on the side of a doubtful ureteral shadow would indicate that the shadow in question was intraureteral. Unless there is considerable dilatation of the renal pelvis, or infection as a result of stone in the ureter, marked diminution will not usually be found. As with renal lithiasis, stones in the ureter giving doubtful shadows in the roentgenogram are usually small and more often cause but little dilatation or infection in the kidney. Consequently, diagnostic diminution in secretion will be found of practical value in but a small proportion of ureteral stones. An equal comparative function, however, would not exclude the possibility of stone in the ureter. In eight cases of stone in the ureter in which the secretion of the urine was not interfered with and the roentgenographic and cystoscopic evidence was doubtful, positive diminution in comparative secretion was found in two cases.

HYDRONEPHROSIS

With hydronephrosis of any considerable size, a marked diminution of function occurs. This is to be explained partially by the fact that the retained fluid in the sac may dilute the dye secreted to such a degree as to give the impression that the secretion is diminished. It will frequently be quite impossible to remove all the retained fluid by means of the catheter so that the functional test will have but little exact value in estimating the degree of renal destruction. As with lithiasis, the degree of tissue-destruction is not parallel with the degree of diminution of functional output. With a very small hydronephrosis, however, in which a functional test might be of practical value, but little difference in secretion may be found in the two kidneys since the parenchyma is usually but slightly involved.

RENAL TUMOR

When the classical symptoms of hematuria, pain and tumor are present, and a thorough cystoscopic examination is possible, the condition of renal tumor can usually be readily recognized. Renal neoplasm, however, will frequently occur without any urinary symptoms, and examination of the urine catheterized from both kidneys may be found to be normal. In such cases, a marked diminution of the amount of dye secreted by the side in which the tumor in question is situated would suggest its intrarenal nature. In twenty-nine cases of renal neoplasm in which the phenolsulphonephthalein was employed, marked diminution was found in nine. With infected neoplasm, the proportion of kidneys with tumors showing a diminution in secretion would be greater. However, the cystoscopic evidence of infection from the side of the tumor would usually render a diagnostic functional test unnecessary.

ESSENTIAL HEMATURIA

In the fourteen cases of essential hematuria in which the phenolsulphonephthalein test was successfully employed, no marked comparative diminution of dye-secretion from the hemorrhagic kidney was noted. If there is any diminution of dye-secretion in the kidney from which the hemorrhagic urine is secreted, some condition other than the so-called essential hematuria is present and surgical exploration is indicated. The other conditions which may cause hematuria can usually be ascertained by the various other means of investigation at our command. Nevertheless, the method will not infrequently be applicable in the differential diagnosis of hematuria accompanying the following conditions: (1) renal tuberculosis of the hemorrhagic type without other clinical or cystoscopic evidence; (2) renal neoplasm which causes no recognizable tumor; (3) renal stone with negative Roentgen-ray findings, and (4) chronic pyelonephritis. It must, however, be remembered that any one of these conditions may be present even though no marked diminution in function is apparent. The technical difficulties accompanying ureteral catheterization as the result of marked hematuria will frequently render the comparative functional estimate unsatisfactory.

ATROPHIC KIDNEY

The only condition in which an estimate of the secretory capacity of the kidney by means of cystoscopic inspection and ureteral catheterization might be incorrect would be with an atrophic renal condition as Geraghty has demonstrated. Atrophy of the renal substance to a variable degree is not an uncommon condition. In a series of eighty-one kidneys removed at post-mortem and at operation which showed a variable degree of atrophy, Simpson of the Mayo Clinic found that the condition was due to inflammatory changes in practically every case. Atrophy of the kidney which could not be accounted for by secondary inflammatory change was not found in this series. When a cystoscopic examination was made, attention was usually called to the condition by the absence or marked diminution in amount of the secretion or by the gross character of the urine secreted from the affected kidney. In two cases in which a surgical condition was present in one kidney, a clinical diagnosis of insufficiency of the other kidney was made from very apparent clinical evidence of renal insufficiency. This leads us to believe that a condition of atrophy in a kidney to a degree that it will not sustain life, when the only evidence of its existence can be ascertained by demonstrating that but a trace of the injected dye returns, while possible, must be exceedingly rare. With a surgical kidney on one side and a markedly atrophic kidney on the other, the clinical evidence of renal insufficiency alone will usually render the case inoperable. Data ascertained through cystoscopic examination will, with rare exceptions, give us the necessary corroboratory evidence. That we are correct in our premises is proved by the fact that among the 485 cases in which nephrectomy was done, atrophic kidney was never found as the cause of death.

RENAL INFECTION

Geraghty has called our attention to the fact that the phenolsulphonephthalein test is frequently of practical value in differentiating between an infection largely involving the renal pelvis and one which affects the renal parenchyma to a marked degree. Occasionally, an infection with a low functional return will become practically normal after treatment. With bilateral pyelonephritis, however, the phenolsulphonephthalein output will frequently remain practically normal, and still the patient may give unmistakable clinical evidence of renal insufficiency. Two patients were observed with a bilateral colon infection in whom the first phenolsulphonephthalein output in two hours was 13 and 15 per cent., respectively. After treatment, the infection was greatly reduced and, with the improvement of clinical symptoms, the phenolsulphonephthalein increased to 36 and 45 per cent. With bilateral pyelonephritis, a marked diminution in phenolsulphonephthalein secretion from one kidney would indicate considerable destruction of kidney tissue. With hematogenous septic nephritis, marked diminution from the kidney affected should be expected. It was found markedely diminished in one case in which it was tried.

RENAL TUBERCULOSIS

With early tuberculosis where the tubercle bacilli have been demonstrated in the mixed urine and where cystoscopic examination and ureteral catheterization are unable to localize the disease, a marked comparative diminution of phenolsulphonephthalein on one side should localize the disease to that kidney. In one case which came under our observation, however, in which a circumscribed tuberculous process was present in the kidney, the difference in secretion between the two kidneys was practically negative. When because of technical difficulties it is impossible to catheterize only the diseased kidney and the character of the secretion from the other side cannot be determined, as not infrequently happens in a tuberculous bladder, if the combined phenolsulphonephthalein is over 40 per cent., one might usually infer that the other kidney is healthy. We have observed, however, one case of well-advanced bilateral tuberculosis in which the combined phenolsulphonephthalein output was 66 per cent. in two hours. On the other hand, we have noted several cases of unilateral tuberculosis in which the combined phenolsulphonephthalein secretion in two hours was between 25 and 35 per cent. prior to operation. Following nephrectomy, the patients made uneventful and complete recoveries, and in one case the function rose to 60 per cent. three months after operation. It has been declared that the phenolsulphonephthalein test is of considerable value in cases of bilateral tuberculosis when it is impossible to determine from the character of the secretion which of the two kidneys is more diseased. Removal of a tuberculous kidney in bilateral tuberculosis is indicated, as a rule, only when one kidney is practically destroyed and the other slightly involved. It has been our experience that if on cystoscopic examination one is unable to determine from the character of the urine secreted which of the two kidneys is largely destroyed, operation is contra-indicated.

PERINEPHRITIC ABSCESS

Marked comparative reduction in function may be the only evidence present to identify the origin of a mass palpable in the perirenal area. Perinephritic abscess of renal cortical origin may be present without any pathologic evidence in the usual examination of the urine. Marked diminution in secretion of phthalein was noted in two cases of perinephritic abscess where the catheterized urine was negative save for an occasional pus cell. In one case, however, there was no appreciable diminution present. From this it may be inferred that a perinephritic abscess may be of renal origin in spite of equal functional output.

POLYCYSTIC KIDNEY

A marked diminution in phenolsulphonephthalein secretion occurs with polycystic kidneys only when the destruction of renal tissue has advanced to a considerable degree. When the disease is well advanced, clinical evidence of renal insufficiency is usually manifest. In seven cases of polycystic kidney, a phenolsulphonephthalein secretion of less than 40 per cent. occurred in but two cases. In two cases a comparative reduction in phenolsulphonephthalein excretion proved to be of considerable value, however, in determining in which of the two kidneys the greater degree of destruction had taken place. This may not always be ascertained by the comparative amount or character of the urine collected from the individual kidneys.

CONCLUSION

We should like to emphasize that it is not our purpose to belittle Geraghty and Rowntree in their thoroughly scientific efforts to establish a chemical estimate of renal function. The phenolsulphonephthalein test, because of the ease of application and rapidity of secretion, remains as probably the best functional test at our command. Nor is it our purpose to detract from the value of a careful examination of the character of ureteral secretion in surgical conditions of the upper urinary tract. It is our contention, however, that the fundamental surgical principles and clinical data should determine whether or not an operation is indicated; and that renal functional tests are of practical value largely as an aid to differential diagnosis and only to a limited degree as a prognostic aid.

ABSTRACT OF DISCUSSION

Dr. John T. Geraghty, Baltimore: I fully endorse Dr. Braasch's view that functional tests should not be employed to the exclusion of all other methods. The employment of functional tests cannot give us the diagnosis of itself, nor always the prognosis. When taken in conjunction with the data obtained from careful clinical examination, however, they furnish information which is valuable and frequently not obtainable in any other manner. We have never attempted to draw a line beyond which one should not operate, but when we find, in cases of enlarged prostate, a very low renal function as indicated by phthalein, every effort is made by careful preliminary treatment to improve the functional condition of the kidney before operation is undertaken. At the present time we employ two tests; the phthalein for the estimation of the excretory function of the kidney and, when this is found to be very low, an estimation of the blood-urea is also made. When the phthalein is high and the excretory capacity of the kidney good, there is no necessity of doing a blood-urea because this will be practically always normal. Given a patient with a very low phthalein excretion and a high retention of non-protein nitrogen, his condition can be considered critical regardless of the clinical appearance, and such a patient is a bad operative risk. A knowledge of the renal function is of value not only because it enables us to select the most favorable time for operation so far as the kidney condition is concerned, but it frequently influences us in the method of procedure and in the choice of anesthesia.

Dr. B. A. Thomas, Philadelphia: I concur most heartily in what Dr. Geraghty has said. I would also call attention to the fact that we should not blame the functional kidney-tests for errors in surgical practice that may occur and also for not carrying out the best postoperative technic. I have felt for a number of years that the simple total quantitative output by a patient on any particular day was not to be viewed with entire satisfaction with respect to the operability of the case. Consequently I believe that, practically without exception, for the surgeon who wants to get a line on the kidney function, whether bilateral, unilateral or total, the indigocarmin test is a serviceable one and one in which the deductions are immediate (chromo-ureteroscopy), concise and reliable. If, however, it be advisable for any particular reason to supplement chromo-ureteroscopy with more extended observations, I believe that, in order to determine the stability of the kidney function and in order to determine whether or not the patient is gradually improving and reaching an operable condition from one which was inoperable at the time of his admission to the hospital, greater reliance can be placed on the method to which I previously called attention, namely, the index of elimination. The index can be applied not only to indigocarmin, but to any substance used in the capacity of a functional kidney-test. If the kidneys are diseased the onset will be delayed, the amount eliminated in the first hour will be diminished, and consequently the relative output for the succeeding hours will be increased. Therefore, if we compute the index of elimination by a study of the third hour as compared with the first hour, we will arrive at a means by which the stability of the kidney function can be determined, and improvement in the course of the case with respect to operability can be determined. If the output of the third hour equals or exceeds that for the first hour—unless the total amount exceeds 20 per cent. for the three hours—that case must be viewed with concern by the conscientious surgeon, with respect to its operability.

Dr. George G. Smith, Boston: If I understood Dr. Braasch correctly, he said that in certain cases the healthy kidney will have a reduced function because of the toxins from the other. Has Dr. Braasch noted definitely that this occurred in any considerable number of cases? Because in the experience which I have had (a great deal less than his, it is true) I have not seen, or have not recognized it. Whenever I have examined a pair of kidneys, one of which was diseased, I have found that the healthy kidney has had a rather better function than one of two normal kidneys would have, and it has never shown any reduced function because of disease of the other kidney. It is true that its function will increase after the diseased kidney is taken out, but I should not say from my experience that the absolute function, if one might use that term, of the healthy kidney has been reduced by the disease of the other kidney. In interpreting the phthalein test, as with all similar tests, we must remember that the findings indicate simply the condition of the kidney at one particular moment, and that the condition of the kidneys is influenced to a large degree by the condition of the patient. I have in mind a boy who had a calculus pyonephrosis on one side and on the other side a small stone, with a severe infection and pyelonephritis. He was admitted to the hospital from the outpatient department. He first had an intramuscular injection of phthalein. We obtained 18 per cent. in the first hour. He became worse during the night, his temperature went up, and we were not sure of the condition, and on catheterizing the ureters next day we found almost no function from either side. He was operated on the following morning and a bilateral nephrostomy done simply for the purpose of getting kidney drainage. We found that he had a calculus pyonephrosis on the right side and on the left an acute focal suppurative nephritis. The left kidney was apparently going to pieces very quickly, and I think that explains the sudden decrease of the function on that side. This case simply points the moral that this test, like all others, must be interpreted in the light of other facts. The general condition of the patient, the condition of the urine obtained from the kidney, the blood-pressure—all these things must be taken into consideration, and the test must be interpreted with common sense, and not regardless of the other factors in the case.

Dr. William E. Stevens, San Francisco: I would like to ask Dr. Braasch if he used any of the other tests of excretion at the same time that the phthalein test was used. It seems to me that there is a tendency at present to abandon recklessly all other tests in favor of the phthalein. In a rather large number of experiments during the last two years we have found the phloridzin at least of equal value with the phthalein test. They have been applied simultaneously, the phloridzin first, followed by the phthalein. In some cases the phloridzin test has seemed to be of greater value than the phthalein test.

DR. W. F. BRAASCH, Rochester, Minn.: I have occasionally employed methylene blue and indigocarmin as an aid in finding the ureters and have also used it to ascertain approximately the kidney function when we have been unable to catheterize the ureters. The question has been raised whether the healthy kidney increases its function following the removal of the diseased kidney. Although increase in function does not always follow, nevertheless I have observed it repeatedly. Dr. Geraghty and I differ only as to the comparative value of the functional test and the clinical examination, in determining whether or not to operate. It has been our experience, particularly in cases of urinary obstruction, that the clinical evidence is the deciding factor which should determine when the patient is to be operated on. As a result of bladder drainage in the first step of preliminary treatment, the patient will invariably have abundant clinical evidence of renal insufficiency if any such is present. The patient will lose in weight and strength and complain of loss of appetite or nausea and show other clinical symptoms of renal insufficiency. When the clinical symptoms improve, after a variable term of bladder drainage and irrigation, when the patient gains in weight, eats and sleeps well and it is evident that the general vitality is improved, then is the time for operation. Although the preliminary treatment and observation is necessary, the method in which the prostate is removed and the details of the after-care are factors of equal importance in making a successful operation. In other words, clinical observation, the preliminary treatment, the operative technic and the after-care are the factors which bring about a low mortality with prostatectomy, and not reliance on any chemical test of the functional output of the kidneys.

THE TREATMENT OF ADVANCED TYMPANIC DEAFNESS

CLINICAL OBSERVATIONS BEARING ON THE PROBLEMS INVOLVED *

PHILIP D. KERRISON, M.D.
NEW YORK

The title of this paper is clearly open to criticism. Deafness is a symptom and not a disease. To the patient, however, the symptom is the disease, and our treatment is of value to him only in proportion to its influence on audition. Applying the same test, are we as aurists satisfied with our results? Taking as a standard the treatment as outlined in text-books and as practiced in most aural clinics, can we claim as the net result the actual relief of a reasonably large percentage of cases?

While this paper is concerned chiefly with one type of deafness—that is, the deafness of ossicular rigidity—it may not be amiss to mention briefly some of the commoner forms of deafness from other conditions:

1. Deafness due primarily to a lesion of the labyrinth or auditory nerve. Such lesions are fortunately rare as compared with those of tympanic origin. They are not amenable to local treatment.

2. Deafness due to otosclerosis. Whether this lesion is confined to the bony capsule or invades the membranous cochlea, the deafness is not influenced by local treatment.

3. Impairment of hearing due to obstructive lesions of the eustachian tube. Functionally these cases are characterized by moderate impairment of hearing, changing noticeably with external conditions (weather, etc.); and responding favorably and more or less permanently to effective treatment of the nasopharyngeal and tubal lesions.

4. Impairment of hearing due to chronic hypertrophic otitis media. In this lesion the mucous membrane lining the entire tubotympanic tract is thickened and congested. Hearing is improved by rational treatment of the eustachian tubes, but rarely, if ever, regains the normal standard.

I shall not attempt, however, to discuss the types of deafness above defined. They are mentioned chiefly to bring into clearer relief the type of which I wish to speak, namely, the obstinate form of deafness associated with intratympanic fixation of the ossicles. And since an analysis of cases will show nearly all cases of advanced tympanic deafness to fall under this head, their clinical importance must be obvious.

STAPEDIAL FIXATION

Fixation of the stapes may be primary or secondary; that is, primary when due to morbid changes which bind the foot-plate or crura of the stapes directly to the margins of the oval window or niche; or secondary when the stapes, though free within the oval window or niche, is nevertheless immobilized through fixation of the malleus or incus, or both. So far as I have been able to determine, the type of deafness does not vary materially with the particular section of the ossicular chain which is bound within the tympanum, nor with the nature of the mechanical obstacle to free ossicular movement; that is, provided the net result is to prevent transmission of sound waves to or through the foot-plate of the stapes. On the other hand, evidence is not wanting that deafness due to direct stapedial fixation is less influenced by treatment of any kind than is the deafness of same grade and type resulting from checks on ossicular mobility not centered in the fenestro-stapedial joint.

The most characteristic and, so far as local treatment is concerned, the most hopeless type of direct fixation of the stapes is that which occurs in otosclerosis. As the characteristic functional sign of this condition we have Bezold's well-known syndrome, namely, (1) marked diminution of hearing of the lower tones of musical scale; (2) prolonged hearing by bone conduction, and (3) reversed ratio of hearing by air and bone conduction (reversed, or "negative," Rinné). We now know, however, that exactly the same functional reactions must inevitably result from any lesion confined to the conducting mechanism which seriously interferes, either directly or indirectly, with movements of the stapes.

Excluding suppurative lesions, we may mention the following tympanic conditions which not infrequently lead to ossicular rigidity, or fixation:

1. As a result of prolonged subacute exudative inflammation of the tube and tympanum, the tubotympanic mucosa undergoes marked thickening. According to Politzer, the labyrinthine windows are selective regions in which the hypertrophy, or in some cases actual deposition of new connective tissue, is often particularly marked. Theoretically it is conceivable that this process in the region of the oval window may reach a stage causing great reduction of stapedial mobility, later, under treatment or without it, undergoing recession with partial or complete restoration of hearing. This, I am convinced, is a process which explains the considerable and permanent gain in hearing which follows rational treatment in some cases.

---

* Read before the Section on Laryngology, Otology and Rhinology at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914

2. As a result of prolonged tubal catarrh with deflation of the tympanum, permanent contraction of the tensor tympani muscle may react unfavorably on the movements of the stapes by reducing the mobility of the entire ossicular chain.

3. In the course of a chronic or subacute tympanic inflammation of long standing, with occasional acute exacerbations, adhesive bands are formed between the head and crura of the stapes and the walls of the oval niche; or between the head and crura of the stapes and the long arm of the incus. Similar bands may bind the long arm of the incus to the inner tympanic wall or, occurring in the vault, may bind the head of the malleus and body of the incus to the outer bony wall of the attic. According to Shambaugh,[1] these bands may represent folds of normal mucous membrane which, during acute inflammatory change, becoming adherent, are later converted into fibrous bands, these ultimately undergoing strong and permanent contraction.

I have long believed that the presence of a reversed or "negative Rinné" in any case of deafness should be regarded *per se* as evidence of stapedial fixation. In other words, labyrinth and nerve lesions do not as a rule disturb the relation of air and bone conduction; and tympanic changes which do not seriously obstruct the movements of the stapes, do not cause reversal of the ratio between the bone conduction and air conduction of sound waves.

Let us review briefly the routine treatment for this type of deafness as practiced in most aural clinics. Ordinarily, it would be somewhat as follows: The ears are inflated by catheter, the condition of the tubes being carefully noted. If the auscultatory signs show clearly the existence of a condition of tubal catarrh, local applications of astringent drugs to the pharyngeal mouth of the tube are made use of. If tubal obstruction of more obstinate type is found, the eustachian bougie or sound is employed. When the tubes have been restored to a more normal condition, or in any case after a few weeks of treatment, the hearing is retested. Frequently a moderate improvement of hearing is found. With a view of obtaining further functional gain, the patient is ordered to return at regular intervals—once, twice or three times a week, according to the physician's views—and at each séance, whatever else is done or omitted, *the ears are inflated by catheter.*

An experience of years with catheter-inflation has convinced me that the frequent routine use of the catheter *as a means of correcting ossicular rigidity* is based on a false conception of the mechanism involved. The theory on which it is used is, of course, obvious, viz., that the act of inflation moves the drum membrane and with it the ossicles, thereby tending to restore their normal mobility. The beginner in otology is often enthusiastic over the distinct functional gain following a first or second inflation, and is at a loss to explain his failure by the same means to obtain continued and progressive improvement of hearing. The explanation of this phenomenon is that the first few inflations in the case of an individual whose ears have not been under recent treatment often do result in the breaking or at least modifying of small intratympanic adhesions, with consequent improvement of sound transmission. If continued as a routine measure the force of the inflations are exerted more and more in the direction of stretching the drum membrane while exerting progressively less influence on the ossicular chain. Used too frequently or too forcibly, and continued over a considerable period of time, the net result is a disturbance of the tone or balance of the conducting mechansim far outweighing the influence of the comparatively small passive movements of the ossicular chain. There is no question that the victim of chronic middle-ear disease may suffer further permanent disturbance of function as a result of excessive or irrational routine catheter inflation.

The first rational indications of treatment having been carried out, there remains in these cases a variable degree of residual deafness which represents the real problem of the disease.

In referring to a few experiments in the direct examination of the ossicular chain through an incision in the drum membrane, I wish to state most emphatically that this procedure is not advocated as a therapeutic measure for the improvement of hearing. The results, either negative or otherwise, are cited solely for the possible light they may throw on the lesions and the resulting deafness.

EXPERIMENTS

Case 1.—N. W., a boy of 17, first seen in August, 1912, suffered from bilateral deafness for which, during the three years preceding, he had gone from clinic to clinic, the deafness meanwhile becoming progressively worse. When first seen by me, he was so deaf that he found it impossible to obtain work, or at least to retain any position.

Examination.—Both drum membranes were retracted and presented the white, opaque areas usually ascribed to calcareous deposits.

Hearing Tests.—Acoumeter (all metal and somewhat louder than the instrument usually sold), right ear, 3 feet; left ear, 16 inches.

Loud whisper, right, 2 feet, with errors; left, 1 foot with errors.

Lower tone limit, right ear, 60 d.v.; left ear, 128 d.v.

Upper tone limit, slightly lowered in both ears.

Bone conduction, 256 fork, markedly increased in both ears.

Rinné, reversed ratio in both ears.

Weber test, not lateralized.

A noticeable feature in this case was the disproportionate loss of hearing for conversational speech as compared with other functional reactions. On account of this disabling feature of his deafness, I advised him to take up seriously the study of lip reading. This advice was not well received, the patient contending that if nothing could be done to improve his hearing he could not make a living. He was accordingly placed on the usual routine treatment.

In December, 1912, the loud acoumeter[2] was heard as follows: Right ear, 5 feet; left ear, 2 feet. For all practical purposes, however, his hearing was in no way improved, and the patient was deeply despondent. I therefore told him that I would like to investigate the condition of his ossicles through an incision in his drum membrane, but could do so only with the distinct understanding that such a procedure would be altogether experimental. To this proposition he readily agreed.

Surgical Measures.—The instruments, a scalpel-shaped myringotome, blunt hook, and probe with a distal or terminal notch, were especially ordered for this case.

January 8, 1913. The left canal and drumhead were cleaned with alcohol and dried, and a pledget of cotton, dipped in a 10 per cent. solution of phenol (carbolic acid), was placed against the drum membrane and removed after

---

[1] Shambaugh: The Journal A. M. A., Sept. 27, 1913, p. 1206.

[2] The acoumeter which I have used in these tests is made entirely of metal, emitting a somewhat louder sound than the usual rubber-encased instrument. In testing the very deaf, such as are referred to in this paper, I have found it convenient to strike the short lever forcibly with my finger, thus eliciting the maximum sound, which again is louder than that produced in the prescribed way. It is in reference to these facts that I have used the term, "loud acoumeter," in this paper.

about two minutes. A nick in the posterior segment, just behind and parallel with the hammer handle, caused little pain and little or no bleeding. A cotton pledget saturated with 10 per cent. solution of cocain was placed in contact with the drum membrane, the head tilted toward the opposite shoulder, and the air in the auditory canal compressed as in the fistula test. Two minutes later, the tympanum was quite anesthetic. The nick in the drum membrane was now extended upward and downward along the posterior margin of the hammer handle. The hook, pointing downward, was next introduced and rotated so as to engage the hammer handle, and slight traction used. So far as any sense of "give" or yielding could be appreciated, the ossicular chain, or at least the malleus, seemed firmly fixed. By gentle traction I could draw the patient's head toward me, and I received the impression that any excessive force would result in fracture of the hammer handle rather than rupture of its ligamentous or fibrous attachments. That no excessive movements of the stapes occurred was shown in this case by absence of nystagmus or of marked disturbance of equilibrium. Several minutes of intermittent traction produced a slight sense of yielding of the hammer handle but no sudden breaking of any adhesion or constricting band that I could appreciate.

Tests immediately after this experiment showed the loud acoumeter to be heard 14 feet, an increase of 12 feet. Hearing for other sound was also increased, the patient himself being sufficiently impressed with the practical nature of the change to request a similar investigation of the right ear. Accordingly, on January 17, the right ear was subjected to the same treatment, with similar results, the hearing distance for the acoumeter being increased from 5 feet to 20 feet.

In the attempt to maintain this result it has been necessary to repeat the manipulation of the ossicles many times in both ears with the following results: In the right ear the hearing distance for acoumeter seems to be stable around 20 feet; in the left ear, it is subject to variations, or relapses, falling at times to 4 feet or less, and going back under treatment to 15 feet. The lower tone limit which was 60 d.v. in the right and 128 d.v. in the left ear, is about 48 d.v. in both ears. In the right ear, which seems to be the least subject to variation, a perforation in the postero-inferior quadrant of the drum membrane seems to be permanent, and this may be a factor in the functional change. Hearing for conversational speech is still very poor though sufficiently improved to enable him to hold a position whereby he earns support.

This case is certainly not cited as a remarkable restoration of hearing, for the patient still has difficulty in interpreting the human voice; and one cannot be sure that the functional gain, so far maintained, may not later be lost. The point I wish particularly to make is that by this method of examination I was able in this case to demonstrate a degree of rigidity involving apparently the entire ossicular chain, for which the usual treatment by inflation, etc., would be not only useless, but irrational and therefore contra-indicated.

CASE 2.—A. S., a girl of 20. Disabling deafness of type characteristic of stapedial fixation, plus physical signs of chronic middle-ear disease. Passive movement of hammer handle by method described in Case 1, showed malleus to be fairly movable. This was followed by a moderate improvement of hearing which, however, was quickly lost, the hearing receding to its previous status. Repetition of this procedure brought the same sequence of events.

Deduction: From the comparatively free mobility of the malleus and its relatively small value in sound transmission, I conclude that this was a case of otosclerosis masked by intercurrent chronic tympanic disease. Passive movement of malleus produced moderate temporary improvement of sound conduction, but in no way influenced the osseous fixation of the foot-plate of the stapes.

The futility of inflation in such a case would seem hardly to require argument.

CASE 3.—This was a typical case of otosclerosis, with Bezold triad syndrome well marked, drum membrane fairly normal in appearance and tubes of normal patency. The deafness was very advanced and the patient had been subjected to much useless treatment.

Passive exercise of the ossicles was tried in this case solely with the purpose of gaining any light which this experiment might throw on such a lesion. As might be expected, it proved practically without influence on audition.

CASE 4.—This case was that of a young woman with extreme deafness. Drum membrane on right side was thin, transparent and retracted giving an unusually clear picture of the oval niche and incudo-stapedial joint. What appeared to be fibrous bands passing from stapes to wall of oval niche seemed to show graphically the nature of the obstacle to sound transmission. A hospital colleague who examined the case with me considered it a particularly favorable case in which to attempt the release of the stapes by the breaking up of the constricting bands. This I attempted to accomplish through forcible passive movements of the malleus. The results as measured by any influence on hearing were absolutely *nil*.

This and the preceding case are cited solely in support of the proposition that there are degrees of direct fixation of the stapes, however produced, which are absolutely uninfluenced by even the most direct and forcible movements of the malleus. Under such conditions the futility of inflation and the usual method of local treatment should be generally recognized.

With regard to the cases of purely tympanic deafness—that is, those to which the popular terms "chronic catarrhal" or "chronic adhesive" are applied—it will be safer to generalize. It would be easy to cite a few cases of spectacular but purely temporary improvement of hearing, but such citations might lead to quite erroneous conclusions.

With reference to the varying character of the impediment to sound conduction, the following brief notes of conditions observed may be of interest: In one case of advanced deafness the malleus, which seemed quite rigid, suddenly yielded under gentle traction as from the rupture of some adhesive process. Coincidently with this, the patient stated that all sounds seemed unusually loud and that sounds now came to him which he had not heard for years, e.g., the friction of his shoe on the floor. Hearing distance for the acoumeter was increased from 3 to 15 feet. I naturally hoped that I had obtained an unusual result for this patient. Even before the drum membrane healed, however, there was a recession of hearing power, the entire gain being soon wiped out. On repeating the experiment, I was rather surprised to find the malleus still freely movable. This time, however, passive movements of the hammer handle did not bring a similar gain.

What occurred in this case I take to have been as follows: My first passive movements broke up simultaneously separate adhesive processes involving the malleus and the incus, or more likely the malleus and the incudo-stapedial joint. Following this, the free mobility of the malleus was maintained, while the adhesive process involving the stapes was quickly reformed; and this after its reestablishment, was no longer influenced by passive movements of the now relatively detached malleus.

In more than one case I have found what seemed a fairly movable malleus, passive movement of which produced an appreciable though comparatively moderate and purely temporary gain in hearing. This condition I interpret as the sign of direct fixation of the stapes within the oval window or niche. This hypothesis, if correct, would support the conclusion that there are grades or types of stapedial fixation which cannot be corrected through *movements transmitted through* the malleus and incus, and for which inflation would be obviously worse than useless.

In other cases in which I could not detect any change in the condition of the ossicular chain as a result of my manipulation of the malleus, there was, nevertheless, a pronounced immediate gain in hearing. In such cases there are two hypotheses which might explain the functional gain, viz., (a) that I had broken or modified existing adhesions so as to allow of better response to sound waves; or (b) that the constringent effect of the cocain on the swollen, or congested, tympanic mucosa may have led to better sound conduction. It is clear that the differentiation of these two influences might easily have been made had I retested the hearing after incision and use of cocain and before my manipulation of the ossicles. Such a differentiation might throw some light on the treatment of certain cases.

To return to the influence of this procedure on hearing: I have in many cases obtained an immediate gain *in hearing quite out of proportion* to what would have been possible by other means. If I were able to report that these functional gains were in general as permanent as they were in some cases spectacular, there is no doubt that we would have a valuable means of treating certain types of deafness. Unfortunately I am obliged to report that the results in most cases were not permanent. There has been no other case in which a functional gain comparable to that reported in Case 1 has been maintained; and the ultimate results have proved too uncertain, and as a whole of too negative a character to justify its mention as a therapeutic measure for the relief of deafness. On the other hand, the very unusual temporary gain obtained in certain cases would seem to indicate most clearly the need of further investigation, by any rational means, of the actual mechanical obstacles to sound transmission. Only along such lines will any real advance be made in the treatment of advanced tympanic deafness.

TREATMENT

Any detailed account of treatment would be as futile and wearisome as it would be out of place before the members of this society. Instead, I shall refer very briefly to certain more or less commonly accepted dogmas, belief in which seems to be based more on frequent assertion and repetition than on the observation of actual facts.

1. In relation to the treatment of the eustachian tubes, there are two time-honored superstitions which should be disposed of. The first is that the passage of a current of air through the tube from the catheter or Politzer bag exerts any permanent therapeutic influence on a chronically diseased tube; and the second is that the use during inflation of medicated vapors—e.g., menthol, ether, iodin, etc.—exerts any alterative and beneficial action on the tubal mucosa. Evidence of the value of either of these agents, so far as chronic tubal lesions are concerned, is wholly wanting.

The minutiae of the treatment of diseased tubes—whether by bougies, sounds, electrolysis, the local use of drugs, etc.—do not call for special discussion here. All have their value in the presence of certain conditions which are recognized by all experienced aurists. Eustachian bougies, while of great value in certain conditions, simply exert pressure the effect of which in many cases is only temporary. If we associate force *with a bougie which is too large for the caliber of the* canal at the isthmus, a laceration of the mucosa may occur giving rise ultimately to an organized annular stricture more intractable than the original tubal lesion.

In my own experience the treatment having the widest scope of usefulness in chronic tubal lesions is the local application of the silver preparations—chiefly argyrol and silver nitrate. *Yankauer's method of first* cocainizing the entire length of the tube and then making direct application of a 25 per cent. or 50 per cent. solution of argyrol, also throughout the length of the tube, gives the best results.

2. *As to the influence of inflation in advanced tympanic deafness:* If a first inflation is followed by an appreciable improvement of hearing, this may be accepted as an indication that the ears should be inflated at short intervals—preferably on alternate days—until the maximum functional gain shall have been reached. In my experience, progressive improvement can rarely, if ever, be carried beyond the third, or possibly the *fourth inflation*. Beyond this, if the inflations are continued at short intervals and over any considerable period of time, there is likely to occur an ultimate recession, or loss, of hearing power, due to a loss of the normal tone or tension of the drum membrane.

I do not mean to suggest that the use of the inflating apparatus should be altogether abandoned; for even after the maximum functional gain from inflation has been obtained, the catheter is still an essential instrument through which to carry out the local treatment of the tube. In other words, the inflating bag may be an essential and useful instrument when used occasionally and gently for the purpose of determining the condition of the tube, or a harmful and dangerous one when regarded as a means of exercising the drum membrane and ossicles by frequent and forcible inflations.

The *subjective phenomena* following inflation are such as render it difficult for either the physician or the patient to differentiate with certainly between the immediate and the ultimate results. In many cases, following inflation, the walls of the membranocartilaginous tube fall again into contact, their congested condition serving to maintain for a time a positive air pressure in the tympanum. While this lasts, the patient experiences the sense of relief and clearer audition dependent on the more normal position of the drum membrane. As soon, however, as the air in the middle ear is absorbed, the drum membrane resumes its retracted position. Frequent or injudicious repetition of inflation brings further abnormal relaxation of the membrane, with more pronounced retraction, and a progressive loss of hearing. The initial results of inflation are sudden and therefore clearly appreciable; the ultimate results of prolonged *routine inflation* are gradual, insidious and therefore difficult to gage.

My own experience and belief are that more of actual and permanent functional gain can be accomplished through treatment directed solely to the *dis-*

eased lining membrane of the eustachian canals than can ever be obtained by routine catheter inflation.

The correction of ossicular rigidity by some form of non-surgical treatment is a problem of which no satisfactory solution has yet been found. "Pneumatic massage" is a term, formerly in more common use than now, applied to passive movements of the drum membrane by means of any instrument producing alternate condensation and rarefaction of the air in the external auditory canal. It has been widely advocated and tried out, and has been found wanting.

I have long believed that exercise of the conducting mechanism, to be effective, should fulfil two conditions, both of which are violated by the usual form of pneumatic massage, viz.: (1) the membrana tensa should be made to execute movements simular to those induced by sound waves; and (2) the number of vibrations per second should bear some definite relation to that note in the musical scale which marks the lower limit of the patient's tone perception.

With patients whose lesions are confined to the tympanum, I have proved experimentally—at least to my own satisfaction—that the ossicular chain may be thrown into more or less vigorous vibration down to and below the estimated lower tone limit by a system of tuning forks properly designed for this purpose. If impressions of sound reach the inner ear chiefly through vibrations of the conducting mechanism in response to sound waves from without, why may we not make use of selected sound waves to exercise the drum membrane and ossicles in just those movements (sounds) for which their mobility is shown to be impaired? If, for example, it be shown by careful testing with small forks (for example, the Hartmann set) that the hearing is impaired, but not actually lost, for a given note, for example, c (128 d.v.), why is it not a rational and logical procedure to exercise the drum membrane and ossicles for that particular tone by means of a larger fork of the same pitch whose greater amplitude of vibration is sufficient to throw the drum membrane into more vigorous vibration?

The tuning forks employed by me were expressly designed for experiments in the exercise of the ossicles. They consist of a set of large unclamped forks, the prongs of which are ¾ inch wide and as nearly as possible of uniform thickness; the variations in pitch being regulated by graduations in the length of the prongs. They produce all the full tones of the musical scale from C-2 (32 double vibrations) to c^2 (512 d.v.), four octaves higher. They present broad, flat surfaces which when set in maximum vibration and held close to the ear, cannot fail to throw the drum membrane and ossicles into more or less vigorous motion. To illustrate their use, let us suppose a case of tympanic deafness in which the lower tone limit has been roughly estimated by means of the Hartmann set of tuning forks. If, for example, the patient can hear Hartmann c^1 fork (256 d.v.) but not the c fork (128 d.v.), the tone perception is further tested by forks representing the intermediate notes of this octave—that is, 240, 213, 192, 170, 160 double vibrations, etc.—until the correct lower tone limit is reached. For testing purposes the forks should be struck with only moderate force and held with the space between the prongs opposite the ear.

Supposing that the lower tone limit is shown by this test to be neither 128 d.v. nor 256 d.v., but the intermediate tone of 160 d.v., this fork and three or four others immediately below it in the musical scale (that is, 144, 128, 120, 107 d.v., etc.) are employed for exercising the drum membrane and ossicles. Using first the highest fork, 160 d.v., it is set in maximum vibration and held with flat surface of the prong close to the ear until no longer heard. This is repeated ten or twelve times. Then the next fork, 144 d.v., is used in the same way and so on through the series of successively lower forks, until one is reached which cannot be heard even momentarily in maximum vibration. Used in this way tones several notes lower will be heard. Letting the ear now rest for one or two minutes, in ceratin cases an appreciable though moderate gain in hearing will be found.

To guard against possible misapprehension, I wish to state clearly the limitations of this procedure. It obviously cannot be expected to break up old or firmly organized adhesion bands within the tympanum. It may, on the other hand, render certain adhesive processes less rigid and to this extent bring about an increase of joint mobility with proportionate functional gain. It is therefore of greater efficacy in moderate than in advanced grades of functional impairment. It should in fairness be spoken of only in comparison with other advocated methods of combating ossicular rigidity. In this light, its advantages may be stated as follows: In theory it is a rational measure in that (1) it calls for no exaggerated excursions of the drumhead or for movements having no relation to the function of sound transmission; and (2) it forces the drum membrane and ossicles to vibrate in response to just those sound waves, or tones, for which their mobility is known to be impaired.

In actual practice the results have varied considerably in different cases, some being aided while others have shown little or no improvement. As offsetting failures, there have been no untoward results.

In the foregoing pages, I have outlined what in my experience have proved the more practically useful measures in advanced tympanic deafness. It is clear that if we are to make practical headway in lifting the handicap under which many of these patients labor, we must ultimately develop our work along other lines and broaden somewhat our conception of the task before us. We must discard the idea that the hearing by the patient of an acoumeter a few inches or a few feet further from his head, while he is still hampered by practical inability to interpret the average conversational voice, represents a practical success. From the patient's view-point it is a failure; and the only consideration which leads him to regard it as of value to him is the fact that he views this somewhat negative result in the light of a milestone marking what he believes to be his progress toward better results, or as an anchor by which he resists the current toward hopeless deafness.

I have during the past two years given a good deal of time to hearing tests, and particularly to an effort to place our tests of hearing for conversational speech on a more exact basis; in a word, to developing a simple qualitative test, or one showing the relative auditory acuity for the various speech components. These studies have led me to somewhat unexpected conclusions in certain directions having, it has seemed to me, a practical bearing on the interpretation or management of certain forms or grades of deafness. They fall too far outside of the scope of this paper to be included here. They may be made the subject of a later report.

58 West Fifty-Sixth Street.

ABSTRACT OF DISCUSSION

Dr. John R. Page, New York: I recall the particularly brilliant result in the case referred to in the paper. I have intended trying the operation and found one case in which I thought it would be well worth while; but the patient asked if there was any danger attached to it and I said that possibly there was, as I recalled a case in which Dr. Kerrison got considerable traumatism or infection that caused considerable alarm, did you not, Dr. Kerrison?

Dr. Kerrison: Yes, I had one case. Many of the cases had physical signs of acute inflammation. In one case there were mastoid symptoms. It is obvious that there is a chance of infection of the tympanum and, of course, it might go on to mastoiditis, but if you are careful in your technic the danger is slight. All the cases have healed quickly.

Dr. George L. Richards, Fall River, Mass.: How did Dr. Kerrison determine that he got movement of the stapes?

Dr. Norval H. Pierce, Chicago: From Dr. Kerrison's preliminary remarks, I gathered that he cut a hole in the membrane to ascertain the mobility of the stapes. That procedure was tried by Schwartze away back in 1872, I think, and it was discarded, first, because one could not ascertain the mobility of the stapes by touching it, and because Bezold proved that he could demonstrate its fixation by functional tests. He showed that the sound waves get into the labyrinth in two ways; up to thirty-six vibrations they are conducted through the stapes by wave vibration; then, the entire ossicular chain vibrates *en masse* and gradually beyond that it passes in by molecular vibration. He proved this by observations on patients during life and observations after death by microscopic examinations. Therefore I do not believe that we should revive this old idea of cutting a hole in the membrane to ascertain the mobility of the stapes. I have operated in the past, some years ago, in quite a number of cases of what we know now to be fixation of the stapes, and I always failed of improvement, and I have had several results that were very distressing; one in which complete facial paralysis occurred and remained permanent. In several others infection of the mastoid occurred; none that required operation but which caused a good deal of worry. It is impossible, I think, to obtain any permanent results by cutting a hole in the membrane and putting a hook around the handle of the malleus to try to work the adhesions loose. One occasionally gets slight improvement, but it passes away as soon as the membrane heals up. I have had pronounced benefit to hearing from ossiculectomy in cases in which the ossicular chain was demonstrably bound down by adhesions between the promontory and the umbo. One case of this type was particularly instructive; Neuman's method of local anesthesia was attempted. When the cocain was injected under the periosteum in the bony canal, I was surprised to see quite an enormous cholesteatomatous mass project out of the rather small opening in the membrana flaccida and it occurred to me that that might be a very good treatment for certain cases of cholesteatoma. The entire epitympanic space was irrigated and emptied. I got no anesthesia, however, in this case, because the fluid was not retained. General anesthesia became necessary. Before proceeding with general anesthesia, and after washing out the cholesteatoma, I tested the hearing and found it considerably improved. The hearing was increased considerably and permanently by the ossiculectomy and the cholesteatoma was cured. She could hear a whisper only within 3 feet before operation; afterward something like 15 feet. I think we should be careful, however, not again to revive a hope that has long since been buried in our otologic experience, namely, that by merely dividing or breaking up adhesions within the tympanic cavity, especially if they are of any considerable extent, we may obtain permanent, considerable improvement.

Dr. W. S. Tomlin, Indianapolis: I have had some slight personal experience along the line given us by Dr. Kerrison, my attention having been called to it by Ruttin in Vienna. He didn't recommend incision of the drum, but devised a hook which I have used in three cases. In one the result was good and in the other two not so satisfactory. I found it necessary to follow up the operation with the more or less standard treatment for chronic catarrhal otitis media. The treatment may be followed out along the lines following the Heath operation. I have been inclined to consider that in a certain proportion of the cases in which Heath gets increased hearing after his operation it may be due to the fact that he is persistently keeping the middle ear dilated and keeping down adhesions following the operation. We are not able to measure the movement of the stapes, but if we can affect the movements of the malleus and the stapes is not bound, it will move in proportion of inverse geometric progression. While these adhesions have been going on the individual may find that he can increase his hearing by blowing his nose, and in one case I found marked distention of the drum membrane from this cause. In it there was increased benefit by a thickening of the drum following the use of irritants. The indications for the procedure are: (1) of course a reduced hearing; (2) negative Rinné without absolute increased bone conduction; (3) markedly better hearing with audition tube; (4) retracted drum with restricted malleolar movement; (5) the other evidences that the stapes is movable. It has not seemed to me indicated in the presence of active inflammatory processes.

Dr. S. MacCuen Smith, Philadelphia: I doubt if Dr. Kerrison can hope to have any permanent results from this procedure. Some years ago I performed a number of operations, following the example of Sexton and others; there was a series of about 168 cases, and they were, with few exceptions, decidedly spectacular in point of immediate improvement. They were also notable, with several exceptions, from the fact that the subsequent loss of hearing was as rapid as would have occurred without operative interference. Following up the cases in later years, I thought they lost their hearing even a little more rapidly than if I had not operated. I am much inclined to adhere to a memorable saying of St. John Roosa, some years ago: After listening to a number of papers on the improvement of hearing in these cases, he said: "They will probably hear when Gabriel blows his horn, but not before."

Dr. P. D. Kerrison, New York: I wish to make it clear that I had no intention of proposing the method of examining the ossicles described in this paper as a new treatment for deafness. A careful reading of my paper will show that there is no ambiguity of statement and therefore no reason for misinterpreting my meaning on this point. I do believe that the usual management and treatment of these patients is unsatisfactory, and that a revision or an analysis of methods and results is therefore desirable. I agree absolutely with Dr. Pierce's remarks on the treatment of otosclerosis, first because they are logical, and secondly, because they are in accord with my own personal experience. It is evident from the discussion that there has been some misunderstanding of the purpose of my paper. This, I think, has been due largely to the haste and necessity for skipping parts in reading. My meaning will be made clear to those who may read my paper when it appears in The Journal.

The Power of Accurate Observation.—By accurate observation we must mean not the mere exercise of the senses, not the mere seeing or hearing, or touching of a thing, with some levity of thinking about it; we must not mean even the keenest use of the eye cultivated in microscopic work, or of the ear-hearing sounds that to the uneducated sense would be inaudible, or the use of the finger with the most refined detective touch. All these higher powers of the sense you must acquire by careful study practice, and you must learn to exercise them all with all the attention with which a strong will can direct and watch them: But even all this, difficult as it is, is only a part of scientific observation. This must include, besides, an habitual constant watchfulness, the taking notice of all the conditions in which objects or events are found; their concurrence, their sequences, their seeming mutual relations, all their variations.—Sir James Paget.

THE RELATION OF THE RHINOPHARYNX TO THE MIDDLE EAR AND MASTOID *

E. L. JONES, M.D.
CUMBERLAND, MD.

For about one-sixth of a century it has been my custom to treat the rhinopharynx as the main point in most diseases of the tympanic contents, and supplementary measures have varied only with the introduction of new agents, such as epinephrin, argyrol and hexamethylenamin.

Volumes have been written on the relation of diseases of the nose and nasopharynx to middle-ear disease, but my contention is that every case of acute middle-ear inflammation must spring from a pathologic rhinopharynx, however normal or symptomless it may seem, or may have been previously; and our most effective measures must be directed toward treating the nose and removing the cause of the ear trouble.

The cavities of the temporal bone may be looked on as accessory cavities of the rhinopharynx, which by chance happened to contain the organ of hearing, with its complex and vital surroundings. Thus sheltered, the only gateway for bacterial invasion is the eustachian tube, and if this be guarded, few germs are apt to find entrance by the blood-channels. From time immemorial, the dependence of otitis on acute coryza, and pharyngeal infections—whether tonsillitis, diphtheria or the exanthems—has been recognized, and for a generation or more its association with adenoids and grip has been known; but the latent infections from the rhinopharynx, where none of the preceding conditions have been manifest, are only now being recognized. In his recent text-book, Kerrison says he believes that "more cases of acute otitis media result from a simple nasopharyngitis, acting on an individual in whom strongly predisposing conditions exist, than can be traced to all other exciting causes combined." Likewise, in his presidential address before the American Laryngological Society last year, Dr. Leland says: "And since the ear is also an accessory cavity, nine-tenths of whose diseases originate in the mucous membrane of the nose and nasopharynx, etc."

Admitting, as all must, this etiologic relation, what advantage has been taken of it in treatment by the universally taught and practiced methods? If some operation is needed in the throat or nose, we are advised to do it; but opinion is divided as to the advisability of doing operations in acute otitis. Quoting further from Dr. Leland, he "removes adenoids, including Rosenmüller's fossae, during acute stage, to deplete the tissues, thus often obviating the necessity of lancing the drum." Personally, I prefer doing any operation of this character during a quiescent stage, for the purpose of preventing recurrences.

But how about the much more numerous cases in which no operation is indicated? We are told to keep the nares and rhinopharynx washed out or sprayed with mild, unirritating alkaline fluids, to which may be added sufficient phenol (carbolic acid), menthol or essential oil to give a smell suggesting "medicated." In my belief these sprays wash out only a small percentage of germs, and do not make it sufficiently disagreeable to others to cause them to move out. In the plan to be advocated, there is no call for Dobell's solution with its varied formulas, or liquor antisepticus alkalinus, or any of the sweet-scented or pink-tinted proprietaries. As will be set forth further on, this relation of the rhinopharynx to the middle ear applies equally to subacute and chronic cases, and in a measure to chronic suppurative cases also. The number of cases on which conclusions are based could probably be designated with three figures; but I believes these conclusions will be sustained by trial in other hands.

In all cases, whether acute, subacute or chronic, and regardless of the specific cause, the rhinopharynx is mopped, or rather forcibly scrubbed out, with a mixture of phenol, tincture of iodin and glycerin, to which camphor and menthol have been added, of sufficient strength to set up a violent reaction, with painful sore throat, lasting from part of a day to several days. Patients rapidly become accustomed to the effect, so that after half a dozen applications this treatment causes only a passing discomfort. Adults and children are given the same treatment, though in infants under three years old the mixture is weakened. When compressed air is available, self-restraining patients have the nostrils sprayed with a camphor-menthol-iodinized oil; otherwise it is swabbed through the lower meatus on each side, and back to the upper throat on cotton carriers, and the strength is decidedly more.

My two formulas are, first: Fifteen grains each of camphor and menthol are rubbed to a liquid; then 1 dram of compound tincture of iodin, 2 drams of alcohol, and glycerin to make 1 ounce are added. This I call camphor-menthol compound. For spraying it is diluted with nine volumes of hydrocarbon refined oil. Practically this same formula, flavored with cinnamon oil, has been on the market for several years ready mixed under a copyrighted name.

The second formula is 1 part phenol, 1 part tincture of iodin saturated with potassium iodid, and 2 parts glycerin. This is the iodin and acid carbolic compound which I designate I. & A. C. Co.

For swabbing, a fair sized cotton mop is fixed in a strong curved Sims carrier, which is made of nickeled spring brass, or the Ayres modification, made of steel, dipped first in the I. & A. C. Co., squeezed against the bottle neck to remove excess; then dipped in the C. M. Co. and rubbed against bottle neck only sufficiently to prevent dripping. It is quickly thrust behind the palate until it strikes the vault of the pharynx, and then forcibly rubbed from side to side, unless the palate muscles prevent moving it, in which case it is forcibly pressed where it rests. I consider it important to use force in this procedure, as though it were intended to lift the patient bodily on the instrument; hence the need of a heavy stout instrument, and not a bent wire, or other device not permitting great force.

In the painful stage of acute inflammation, or in the acute catarrhal stage without pain, the nostrils are sprayed or swabbed with a few drops of a 2 to 4 per cent. solution of some local anesthetic, and from ½ to 1 drop of 1 : 1,000 epinephrin. This not only contracts the vessels, but it is believed that the sedative effect of the anesthetic on the sensory nasal nerves exerts a beneficial influence on the vasomotor nerves supplying the inflamed areas; this is then followed by the C. M. Co. to the nose, and the I. & A. C. Co. to the rhinopharynx. This treatment is made only once in twenty-four hours, and the patient is not given any nasal spray or throat wash whatever. The only local meas-

ure for home use is the hot-water bottle. If the tongue is coated, a good dose of calomel, followed by salts is ordered; if not coated, the salts only. Since the announcement that the formaldehyd-liberating drugs are eliminated by all the mucous and serous secretions as well as by the urine has been accepted as fact, patients in the acute stages have been put on regular doses of hexamethylenamin. Physiologic chemists assert that formaldehyd is liberated only in acid mediums, but there may be other explanations than the liberation of formaldehyd, of good resulting from this medication.

Several years ago, a formula appeared in some British publication, of a local anesthetic for the inflamed drum membrane, claiming to make lancing the drum painless. I tried it for that purpose, but it was a disappointment. However, I found it to be a most excellent local application, and gradually I have done away with lancing the membrane, so that I no longer make a free incision in the drum first thing, a thing very hard to do properly except under general anesthesia. This preparation is made by dissolving epinephrin (adrenalin chloride, P., D. & Co.) in anilin, 1:1,000, and then making a 10 per cent. solution of cocain in this. Anilin, so-called anilin oil, is a poison, but just how toxic I have never been able to learn; but I have used it in very small quantities, and have not as yet observed signs of anilin poisoning, designated as coal-tar poisoning, as exemplified in overdoses of acetanilid by depression of circulation, blueness of lips, extremities, etc. These symptoms have occurred from absorption when acetanilid was used even as a dusting powder on raw surfaces. Anilin is used in large quantities in shoe-blacking and printers' inks, but only meager reports of harmful effects from handling them have been accessible to me. The reason for the anilin is that it will penetrate dermal membrane, of which the outer surface of the drum consists, softening it to permit the penetration of the epinephrin and cocain, which localize the inflammation to the tympanum. In the course of a few hours, rarely exceeding twelve, there is an abatement of severe pain, and usually inside of twenty-four hours, its entire annulment. In a fair proportion of cases suppuration is entirely aborted; in others, even while fever continues, the pain will disappear, the redness and bulging of the drum diminish, and the impression is created that the suppuration has aborted. Then the drum develops a small perforation and discharges a secretion, mucoid rather than purulent, which ceases in a few days.

The mode of application is to have a loosely twisted swab longer than the auditory meatus, moisten the tip with not more than 1 drop for a child, or 2 drops for an adult, carry it down to the drum, withdraw the wire carrier by a rotary motion, reverse to its winding, and crowd the excess of length into the meatus to bring a slight pressure against the drum, and retain in place; then fill the concha with extra cotton. This is done only once in twenty-four hours, during the painful stage, and one or two days longer. It requires about three days for these plugs to have all the medicament absorbed from them, when left indefinitely in a dry ear.

The result of these combined measures is to localize the inflammation in the tympanic cavity. If there be fluids or secretions which do not drain out through the eustachian tube, which in my opinion they usually do, the anilin will have softened the drum by maceration, and a nice round little perforation, usually the size of a big pin-head, will open in the lower segment of the tympanum, and stay open as long as it is needed, and then promptly close, thus behaving better than incisions which sometimes heal before their work is done. As soon as the painful stage has been passed, one or two days, swabs after the manner described are wet at their ends only with a 25 per cent. solution of argyrol, and left in the ears against the perforation, filling the canal's full length, to act both as a medicament and a drain, and are changed daily for a few times, then at increasing intervals as recovery progresses. Cases which at the beginning present no mastoid tenderness rarely develop any, and the period of discharge does not exceed one week. When there is already mastoid tenderness of only a day or two's duration, it abates usually in two or three days, and the suppuration within two weeks. When the ear has abscessed more than a week or two previously, and the patient has the accepted symptoms of mastoid abscess, it may require nearly a month to heal in patients who finally recover. After the acute stage has passed by a week or more, inflation by the Politzer method is usually added, but I do not believe this to be necessary, as good results are obtained without it. There is steady improvement in hearing, but not so obvious to the patient as a sudden improvement by inflation, which, however, only shows that the integrity of the ventilating system is being restored, and the improvement comes from this restoration, whether inflation be used or not. During the painful stage, patients are instructed to clear their heads and throats by hawking and suction, and not by blowing the nose, which blowing sometimes inflates the tympanum, causing great pain, and also probably driving secretions back into the mastoid. Not a drop of water is ever used in the meatus, and the perfect recovery of these individuals with healed drum, full hearing and no tinnitus is anticipated with just as much confidence as we expect an eye to recover from a properly treated iritis.

For some time it was with feelings of apprehension, and almost of guilt, that medical treatment was persisted with in cases presenting clearly the indications for surgical measures as all authorities give them.

One of the things of first importance in treating almost all acute febrile diseases is putting the patients to bed, or at least keeping them in a warm room; and yet owing to environment it was necessary for me to treat a large proportion of acute ear cases as office patients, some coming considerable distances from surrounding communities, and mostly during the cold months of the year. This necessity is regrettable, but the fact that patients recovered in spite of it adds confidence to the merits of the treatment.

The more recent the mastoiditis, the quicker it yields to treatment, but in quite a number of instances where discharge and constant boring pain have been present for days or weeks, with fever, septic look, sagging posterior wall, tender mastoid, sometimes swollen or with cervical cellulitis, discharge profusely purulent, at times blood-stained, or in chronic quiescent suppurative cases which have flared up with the foregoing picture, the cases have been brought to a favorable issue. Some of the old chronic suppurations have not only quieted down, but had regeneration of drum membrane to the point of closure, and sometimes restoration of hearing previously impaired.

A measure which may have an attractive future has occasionally been resorted to in the most urgent cases for seven or eight years past, the principle of which was based on subconjunctival injections in the eye, with which my experience has been most happy. One-half dram or more of mercuric cyanid, sometimes with a little morphin, was injected, in strengths varying from 1:500 to 1:1,500, under the periosteum over the tender mastoid; quinin and urea hydrochlorid has been used instead of the morphin, and a weak solution of ichthyol instead of mercuric cyanid. So far, the relief of pain and inflammation has been most gratifying and speedy, although the same type of swelling results as follows the injections in the eye. This produces an enormous outflow of protective lymph or serum into the tissues, which in the battle against disease, Sir Almroth Wright compares to a nation's marshaling all its forces at once, and not sending them against an enemy in small detachments. The infiltration subsides in a few days, feeling after it begins to soften as though under the skin was a bag full of pus. So far, no patient has been given over a single injection, and the usual routine of swabbing the rhinopharynx, and draining the ears has been pursued. The two following cases are illustrations of the injection:

Case 1.—Eliza J., aged 35, reported on Nov. 30, 1913, with severe pain in the right ear which had been operated on in Washington several years before by a prominent aurist. There was a deep fissure along the line of the mastoid wound, and the ear-drum was hard to see by reason of swelling and crookedness of the canal. There were fever, rapid pulse, loss of appetite and sleep, and tenderness of tip of mastoid and antrum. These symptoms did not yield to treatment, but increased. The covering of the mastoid became red, swollen and brawny, obliterating the sulcus of old operation, the neck was stiff, pains incessant day and night, fever continuous. The patient was fast losing strength, looked profoundly septic. December 3, an injection of mercuric cyanid with morphin and quinin and urea hydrochlorid was made about noon, and before evening the pain was entirely gone. The patient began to sleep sound, appetite returned, and pulse, temperature and complexion soon became normal. The ear had a slight discharge, which ceased by December 17. A small opening occurred at needle puncture, from which serum discharged for several days. Hearing is restored to normal.

Case 2.—Floyd B., aged 15, reported March 4, 1914. One month previously he had severe earache for two days and nights, followed by subsidence of pain, and discharge lasting several days. After about two weeks the ear began to pain, destroying appetite and sleep, and after three or four days a swelling appeared over the mastoid causing some cellulitis, and pushing auricle forward, in which condition he was when first seen. There were fever, dizziness, rapid pulse and pale, septic appearance. There had been no discharge with the last attack, and the swelling in the meatus prevented sight of the drum. There was marked nystagmus when looking toward opposite ear. It was thought this might be a case of suppurative periostitis. A fine aspirating needle was introduced to the mastoid cortex, and several drops of thick pus were withdrawn. Injection was then made of a dilute solution of ichthyol, which required much force to insert at first, but suddenly the last portion of about 5 c.c. went in without resistance, and it was noticed running out at the nose, thus proving the connection with mastoid cells, either from carious perforation or natural fissure, as in some cases recently reported by Luc. Between early afternoon and evening all pain disappeared, the boy slept soundly for the first time in a week, appetite and color returned, and he came daily as an office patient for treatment of rhinopharynx, etc. To the usual treatment, vacuum suction through the nose was added. For several days he hawked profusely a discharge from the throat, dark-tinged by the ichthyol, and tasting of that drug showing that the mastoid was draining through the eustachian tube. The boggy swelling over mastoid and tallowy infiltration in neck gradually declined, during a week, and he did not have another twinge of pain. The drum when seen was intact, and no discharge appeared from it at any time. The spontaneous nystagmus soon left, but was marked from turning. Hearing is perfectly normal; no tinnitus.

In acute and subacute catarrhal deafness, the same treatment of nose and rhinopharynx is applied, plus inflations by the Politzer method. The restoration of hearing follows in direct proportion to the duration of the trouble previous to beginning treatments, which should be continued at increasing intervals until the maximum of hearing is reached and maintained. It is my belief that the maximum should equal in adults the best it has been within six months previous, and in children in twelve months previous.

In long-established chronic catarrhal otitis media, the limit of prognosis is to prevent further deafness, not claiming to restore lost hearing, or to relieve tinnitus. As a matter of fact, a fair proportion of patients do eventually improve in hearing, and have diminution of tinnitus, or its entire abatement, except when the patient has colds. The longer the disease has existed, the longer this improvement is delayed in showing. Sometimes, after a long course of treatment it will jump up as suddenly as a "jack-in-a-box," but oftener it is six months or a year or more after the treatment has been finished that improvement is first demonstrated, and it may continue to do so for several years following.

In the belief that artificial ventilation of the ear is a matter of minor importance, the eustachian catheter is seldom employed, dependence being placed on the Politzer method. All patients are warned against taking any quinin, salicylates, or salicylate substitutes, such as aspirin, all of which I believe to be detrimental to hearing which has been severely impaired. Several relapses, some irreparable, have been observed from the knowing or ignorant use of these drugs. One patient with acute otitis with mastoid suppuration had a concurrent attack of acute rheumatism in the foot, for which his family physician gave the usual salicylate treatment. The man recovered perfectly from the suppuration, but the ear was hopelessly deafened, and has so remained for several years.

The course of treatment for the chronic cases should represent the equivalent of twice a week for three or four months. Whether this chronic middle-ear disease is due to a low-grade bacterial infection, or toxemia, or something else undefined, surpasses my ken; but if due to low-grade infection ascending through the tube, we are hitting at its source in treating the rhinopharynx.

Cases of almost life-long tympanic suppuration have sometimes stopped from a few throat-swabbings, when aural treatment alone had not been able to bring this about; so that in addition to the routine treatment of chronic suppuration through the canal, the treatment of the rhinopharynx and nares is regularly carried out. This in all probability prevents reinfections through the tubes and brings the same results as are claimed by Yankauer's method of closing them.

First National Bank Building.

ABSTRACT OF DISCUSSION

Dr. Oscar Wilkinson, Washington, D. C.: I would protest against intranasal or postnasal operative procedures during acute otitis. On two occasions I had bad results from operating on patients who were brought in from the country and insisted on operation. In the first, a double otitis media followed removal of the tonsils and adenoids in a child that had a cold of one day's duration. In another case, I operated on the tonsils in a patient who had a cold and a peritonsillar abscess developed on the third day. I attributed both of these infections to operating during an acute inflammation.

Dr. John J. Sullivan, Scranton, Pa.: I disapprove of the methods advocated by Dr. Jones and would mention the case of a man in Scranton who, following this course, has recently had a case in which a double mastoiditis requiring operation resulted.

THE ORIGIN OF LABYRINTHINE REST-TONE *

EDMUND P. FOWLER, M.D.
NEW YORK

I purpose to account for the origin of the tonus which I believe emanates from every functionating static labyrinth, and which in action and in rest assists to orient us in space.

It can be shown that the otolith organs contribute their share toward rest-tonus, besides assisting in determining positions and motions in space both rectilinear and curvilinear. It is known that influences from many other sources aid the labyrinth in its work, but at this time I will ignore all these, as I desire to concentrate the argument on the semicircular canals.

The semicircular canals are so placed relative to each other and to the utricle, in both temporal bones, that endolymph flow cannot normally occur in one canal without influencing the flow in the other two.

Barany[1] has shown that all three ampullae of both labyrinths are in relation with all six eye-muscles of both eyes, and that we can account for the simultaneous contraction of one set of eye-muscles, and the relaxation of another set, due to peripheral stimulations causing nystagmus, only provided there exists a rest-tonus in the cristae of the canals.

Nystagmus is not necessarily more truly horizontal, or truly rotatory when the external or the superior canals are respectively exactly in the plane of rotation; nor as I have observed necessarily truly in the plane of the canal enduring maximum caloric excitations. Moreover, the position to obtain a given nystagmus varies in different people.

It follows that the character of all nystagmus is dependent on certain combinations of ampullae stimulations (+ or —), and that normally one ampulla never alone determines orientation phenomena.

Shambaugh[2] has demonstrated on a fistula patient, that the: "duration of nystagmus = duration of peripheral stimulation = duration of endolymph current." He concludes that this eliminates the necessity for tonus centers to control the duration of nystagmus, and that it is a potent argument for the origin of labyrinth tonus from the hair-cells of the cristae. From Ewald's and caloric experiments, it also appears that Shambaugh's conclusions are correct. Ewald obtained a greater reaction with flows toward the horizontal ampulla, than with those away from it, and in the vertical canals, greater reactions with flows away from the ampullae.

These facts suggested to me an explanation of the origin of rest-tone, and of many phenomena intimately connected therewith.

In passing, please note that in Ewald's experiment, the opposite labyrinth was functionating, whereas in Shambaugh's the opposite labyrinth was destroyed. This circumstance may partly account for the differences in the amount of reaction obtained between to-and-fro currents in Ewald's, and the lack of marked differences in the reaction from such current in Shambaugh's experiment.

From the foregoing I deduce the following:

1. Physiologic endolymph movements excite impulses from the end-organs, which are interpreted as sensation complexes from all the ampullae. If the impulses from the two labyrinths approximately balance (or through practice are balanced by the aid of the coordinating apparatus), no sensation of movement is experienced. Binaural galvanic or caloric reactions with the head anywhere in the anteroposterior vertical plane demonstrate this clearly, as does the rotation of bilaterally non-functionating labyrinths.
2. The body normally receives a sensation-complex (and a tonus) in the anteroposterior vertical plane, approximately equal from its two sides, but in all other positions, various complexes (toni) must be forthcoming, depending mainly on the position of the head. Any other assumption would not account for balance phenomena observed in the various positions of the body.
3. Labyrinth tonus originates from all the labyrinth end-organs. Postdestruction phenomena also prove this to be true.
4. Endolymph stress is amply capable of maintaining static control in rest, as it does so in action.
5. Positive endolymph stress, within the canals at rest, can occur only because of convection currents ever present therein. I have shown elsewhere[3] that convection currents may be caused by disease, and I shall attempt here to explain their occurrence in health, in one or two ways:

1. By a difference in temperature between the inner and outer labyrinth walls. This may be stimulated by binaural caloric irrigations. Under this influence, the moment the head is moved from the anteroposterior vertical plane, there arise marked unbalance phenomena, due to the placing of the canals in one side of the head more nearly in the optimum, and those within the other side of the head more nearly in the pessimum position for caloric reactions. This theory of thermic differences is therefore improbable, in health.
2. By a constant, but variable difference between the temperatures within the ampullae and the non-ampullated portions of the canals. Is such a difference possible?

The temperature of the brain is normally higher than the blood supplying it,[4] and blood-vessels coming from within the cranium contain blood of a higher temperature than do those from without. The internal auditory artery, a branch of the basilar, traverses the inside of the skull before it distributes its blood-heat to the ampullae of the semicircular canals. This heat is transmitted mainly by conduction and radiation to the ampullae, and as the tiny twigs lie along the concavity of the canals, these receive less and less heat the further the vessel courses from its source.

---

* Read before the Section on Laryngology, Otology and Rhinology at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

[2] Shambaugh: Ninth Internat. Otol. Cong., 1912.

[3] Fowler, E. P.: The Effect of Local Autogenous Temperature Variations, Laryngoscope, March, 1914.

[4] Foster, M.: Physiology, p. 477.

Because of the heat, the specific gravity of the endolymph adjacent to the ampullae is lowered, and within every canal not in the horizontal plane a current is impelled by the force of gravity which establishes, and maintains, a stress on the cupulae of all the canals, at all times.

The specific heat of the spongy labyrinth capsule is 0.71, whereas that of the compact inner labyrinth walls is 0.3, which indicates that whereas protection from the sudden external variations in temperature is provided, changed temperature gradients arising from internal heat variations are quickly established. Moreover, the temperature gradients from the ampullae are more abrupt than would otherwise obtain, because the conductivity for heat of the hard bony canal walls is better than that of the surrounding tissues, and it seems as though the temperature within the ampullae would always be higher than the temperatures elsewhere in the canals, because of these facts and because the blood-supply of the outer labyrinth capsule is derived mainly from the tympanic and other vessels, most of which have not traversed the inside of the cranium, and which must contain, in consequence, blood of a lower temperature than the ampullae vessels, and furnish the principal means of heat dissipation for the static labyrinth and its contents. It follows that the endolymph rest-currents will vary directly as the velocities and amounts of the local blood-supply.

If both labyrinths be normal, and the head is inclined in various directions, why do we not, under these conditions, get an unbalance similar to that experienced during binaural caloric irrigation with the head in any but the anteroposterior vertical plane? At first sight it would appear difficult to fathom this mystery.

If normally there exists constant stress from connection currents within the membranous canals, these currents, owing to the position of the canals as regards the horizontal, in all animals, will be during the greater part of life in the following directions:

In the superior canal, toward non-ampullated end, therefore in + stimulation direction.

In the posterior canal, toward non-ampullated end, therefore in + stimulation direction, aided by superior canal flow.

In the horizontal canal, toward ampullated end, in + stimulation direction, aided by superior canal flow.

Note that the flow in all the canals is in the + stimulation direction. I designate the endolymph pressures and flows, + or —, depending on their direction, in, or not in, the direction of greater ampullae stimulation.

The difference between the direction of + stimulation flows in the horizontal and vertical canals may be explained on the theory that end-organs in the habit of furnishing a tonus derived from endolymph flows in fairly constant directions would only respond to such flows, or at least respond to such flows more readily than to absence of, or to minus flows, in either of which latter eventualities relaxation of the usual tension on the hair-cells of the cristae would occur. In many positions of the head, the endolymph convection currents will be reversed in some canals, in others augmented or retarded. Thus untold numbers of flow combinations and a like number of tonus (stimulation) complexes are brought about and in any and every position of the body and head in space a definite suitable rest-tonus is provided for balance and orientation.

The fistula, galvanic, rotation and caloric experiments are all grossly abnormal, and really demonstrate but little except when positive, but a study of these tests reveals nothing incompatible with the theory of convection current control which I have advanced.

Long ago E. Cyon[5] observed that the obstruction by division of one or more of the canals caused transient effects, provided it was not bilateral and unsymmetrical. This can be accounted for only by assuming the presence of a rest-tonus from the cristae, due to constant endolymph stress. The unsymmetrical bilateral nullification of endolymph flow would naturally be more difficult of recoordination, than symmetrical or unilateral nullifications. Caloric experiments also support this contention.

I have observed spontaneous nystagmus which with the vertigo, was distinctly influenced by changing the position of the head. Why does a patient with a recently destroyed labyrinth lie on the sound side? We are told that it is because he can thus increase the resistance to the nystagmus by being in a position better to turn his eyes toward the side of the slow component. Although this is true, it occurred to me that it is also true that in the side position assumed by these patients, all the ampullae of the functionating labyrinth lie at a higher level than their canals, and thus the higher temperature which I believe resides within the ampullae is rendered less potent as an instigator of endolymph currents (rest-tone) than in any other position of the body. The upper labyrinth being dead, but little unbalance phenomena occur.

With total absence of endolymph flow in both labyrinths, no vertigo or nystagmus, etc., can physiologically be aroused, nor can tonus exist.

I have observed many patients in whom rotation failed to elicit nystagmus or vertigo, and yet caloric excitations reacted strongly and readily. I explain this seeming anomaly as follow: these are usually nerve deafness sufferers (often specific cases). Their whole auditory apparatus is below par. Hence the usual analogous canal currents during and following rotations are insufficient to elicit reaction phenomena, whereas unilateral or unsymmetrical bilateral flows, being more irritating stimulation complexes, are wont to give exaggerated reactions. This seems the most probable explanation because normally the caloric tests are the weakest we employ to determine presence of function.

The straight line filaments of critical velocity flow (the working flow of the canals) tend to continue during and after changes in position, and unless the changes are sufficiently sudden (acceleration speed, + or —, sufficiently great) the current changes are so gradual that no motion is sensed. In Shambaugh's case, the flow could not continue on stoppage of the pressure, owing to blockage of the canal tested by inflammatory lesion. Hence nystagmus, flow and stimulation were coincident. In Ewald's experiment, flow and stimulation in the tested canal were coincident, but the opposite labyrinth was acting, and when the stimulation from the fistula pump ceased, this acting labyrinth supplied the stimulation which produced the phenomena.

---

[5] Cyon, E.: Thése de Paris, 1878.

The continuance of the sensation of turning after rotation, or after caloric irrigation has ceased, and the delay in sensing actual rotation, may thus be partly explained by the persistence of critical velocity flow.

There are many other facts which lend themselves to my theory of labyrinth tonus. I mention the following:

In those cases of vertigo due to the so-called autointoxications, high blood-pressure, animal or vegetable or mineral tissue poisons, etc., how can we account for the various forms of vertigo experienced, except by a more or less transient bilateral inequality in the impulse complexes? Surely if the poisons, blood-pressure or other factors were bilaterally equally distributed to the vestibular and other coordinating mechanisms (as they would be through equal blood-supplies to both sides of the head), vertigo could not result. The stimulation impulses from the two sides would balance each other, and simply heighten or lessen tonus. Of course lessened tonus can beget, as can weakness from any cause, lack of normal balance control, but cannot beget, during rest, rotary vertigo. Rotary vertigo, then, can come only from bilaterally unequal or unsymmetrical excitations of the coordinating nervous mechanisms. This is normally possible only through the action of the vasomotor nerves.

The vasomotor nervous system is the great body tone maintainer, and through its control, variations in blood-pressure, nutrition, temperature, etc., are kept within certain bounds. The temperature gradients within the semicircular canals and utricle depend mainly on the size of the labyrinth vessels, and therefore unstable vasomotor phenomena in these vessels will affect tonus poise. Unsymmetrical vasomotor phenomena are common in many patients vertiginously inclined. Vasomotor influences anywhere along the coordinating tracts may cause vertigo, but I maintain that unless these influences be bilaterally unequal it is inconceivable that vertigo will result.

It can be demonstrated by careful rotation and bilateral caloric tests that every subject of vertigo presents a changed and bilaterally unequal sensibility to these labyrinth stimulants. This sensibility may be more marked in one stimulation complex, than in another, and is explainable by the theory of tonus maintenance I have outlined.

Finally I desire to call attention to the fact that within the animal body there exists no canal or system of canals wherein the circulation of fluid is possible that such fluid is in a state of quiescence, and it is improbable that the static labyrinth should prove an exception to this rule. The endolymph must therefore be in constant motion, maintain a stress on the cupulae, and originate the tonus emanating from the ampullae of the semicircular canals.

616 Madison Avenue.

ABSTRACT OF DISCUSSION

Dr. G. W. MacKenzie, Philadelphia: I hardly consider that Dr. Fowler has proved his case and I offer some suggestions. That there is a tonus no one will doubt, for in the event of sudden destruction of the inner ear on one side we observe the effects of the tonus of the other side with nystagmus and vertigo. If galvano-electricity is applied, using the anode, it causes nystagmus in the opposite direction with vertigo. So no doubt there is a tonus that can be measured in milliamperes. Barany and others have been working for years to try to locate just where this tonus is. In the event of acute destruction of one side, even when the internal ear has been removed, we are still able to stimulate the crippled side, showing that there is some tonus beyond the labyrinth. That is one point I offer. Another is that if this constant endolymph flow existed we could not explain a case I cited several years ago before this Section, in which case the external semicircular canal had had a fistula which afterward healed or closed after a more radical mastoid operation had been performed. According to the turning test, a typical reaction was obtained that corresponded to destruction of the inner ear. Had there been such a current as described by Dr. Fowler, the tonus ought also to have been proportionately destroyed, whereas, by reason of the normal galvanic reaction which was present, it was not. Now we do know that the tonus cannot be located in the greater brain, for in animals in which the greater brain has been extirpated the animal reacts the same to all stimuli as in the normal. I think we have just as much reason to locate it in the cerebellum, which regulates the tonus of other parts of the body.

Dr. E. P. Fowler, New York: There are, of course, many points that come to mind in the consideration of this subject. I tried to concentrate the argument on the tonus arising from the canals. There is no question, as Dr. MacKenzie has said, that all factors that have to do with body balance may play a part in the matter of tonus, and I so stated. If one labyrinth is destroyed balance is soon regained. This can occur only if the remaining labyrinth impulses are opposed or balanced by others arising from these factors, or from a throttling of the impulses from the live labyrinth. I have asked all interested in this work to mention any combination of circumstances that this theory will not cover; of course, it is only a theory, and all theories have certain apparent difficulties. So far I haven't encountered a theoretical or actual condition which we cannot explain by this theory. It is at least founded on a solid physiologic basis, and I simply offer it as a theory until further investigations shall prove it true.

THE ATROPIN TREATMENT OF DYSMENORRHEA

EMIL NOVAK, A.B., M.D.
BALTIMORE

In a paper[1] presented to the Section on Obstetrics, Gynecology and Abdominal Surgery at the recent session at Atlantic City, I referred to the possibility that certain cases of uterine bleeding are due to, or at any rate, are associated with, disturbances in the so-called vegetative nerve system. The evidence which I then offered for the support of this view applies with equal force to the causation of other menstrual disturbances as well as uterine bleeding.

In the case of the latter symptom, no important therapeutic result has as yet been yielded by theoretical considerations as to the influence of the vegetative nerve system on the menstrual function. On the other hand, it is interesting to know that, in the case of dysmenorrhea, a definite method of treatment seems to have been suggested by recent studies showing the great importance of the vegetative nerves in visceral physiology. I refer to the treatment of dysmenorrhea by atropin. A number of articles on this subject have appeared in the German literature, but, so far as I am able to learn, it has received little or no attention from American gynecologists.

---

[1] Novak, Emil: The Pathologic Physiology of Uterine Bleeding, The Journal A. M. A., Aug. 22, 1914, p. 617.

The treatment of one form of dysmenorrhea in particular is notoriously inadequate and unsatisfactory. I mean that type which is observed so characteristically in young nulliparous women, and which is so frequently associated with scanty menstruation and sometimes with sterility. We are all familiar with the picture. The pain, often exaggerated by the nervous or hysteric temperament of the patient, is sometimes extremely severe, so that the recurrence of the monthly periods is looked forward to with dread. As a rule the pain is characterized as cramp-like or colicky, beginning a day or two before the actual onset of menstruation, and ceasing when the flow is well established. This form of dysmenorrhea is spoken of variously as "spasmodic dysmenorrhea," "essential dysmenorrhea," etc. Its occurrence is not dependent on the presence of any demonstrable pelvic disease, although in a considerable proportion of cases, the generative organs present a condition of underdevelopment or perhaps of actual infantilism. By some (Herman) the use of the term "dysmenorrhea" is limited to the type of menstrual pain just described, the affection being looked on as a distinct entity. While I do not agree with those who would give the term such a restricted application, it is not my present purpose to enter into a discussion of the varieties of dysmenorrhea and their etiology. Suffice it to say that the atropin treatment, of which I wish to speak, is indicated only in cases of dysmenorrhea of the so-called spasmodic type.

UNSATISFACTORY PRESENT TREATMENT OF SPASMODIC DYSMENORRHEA

The many plans of treatment, medicinal and operative, which have in the past been advocated in the treatment of this troublesome condition indicate that none has been eminently successful. The fact that even hysterectomy is sometimes resorted to shows to what desperate straits gynecologists are sometimes driven in the management of such cases. Of the medicinal agents used for the relief of this form of menstrual pain, those most in vogue are the coal-tar products, the bromids, hydrastis and viburnum prunifolium. None of these has given very striking results. The two drugs which relieve the pain in these cases with greatest certainty and swiftness — morphin and alcohol — possess disadvantages which should practically preclude their employment.

Among the operative measures advised for the relief of the condition, that most commonly resorted to is dilatation of the cervical canal, most frequently by the rapid method. While in a certain proportion of cases this operation is followed by relief from pain, the improvement is often only temporary. Equally unsatisfactory have been the results of the various operations which have been devised by Dudley, Pozzi and others for permanently overcoming the cervical stenosis which many hold responsible for the suffering in these cases. This is not surprising when one considers that there is now little justification for the old theory that dysmenorrhea is due to mechanical obstruction to the exit of menstrual blood from the uterus.

CAUSE OF SPASMODIC DYSMENORRHEA

Without reviewing the various theories as to the causation of spasmodic dysmenorrhea, it may be said that the explanation accepted by the largest number of investigators is that the pain in these cases is due to a colicky contraction — a spasm — of the uterine musculature, so that the term "menstrual colic," suggested by Stolper,[2] is not inappropriate. The exact mechanism involved in this labor-like contraction of the uterine muscle is not known. The numerous "causes" given by text-book writers — hysteria, neurasthenia, anemia, overwork, etc.—are only predisposing factors. It may be added that there are some who consider that the pains are due to "vascular crises" rather than to muscular contractions. The problem is thus in somewhat the same status as that of the mechanism of intestinal colic, which some also consider vascular rather than muscular in origin. The weight of evidence, however, points to muscular spasm as the cause of the form of dysmenorrhea we are now discussing. This view receives perhaps its fullest justification from a consideration of those cases of dysmenorrhea in which the expulsion of blood-clots is accompanied by distinctly labor-like contractions of the uterus. It must be admitted, however, that in most instances of spasmodic dysmenorrhea the menstrual flow is unclotted, and usually rather scanty.

THE ATROPIN TREATMENT

The use of atropin in the treatment of spasmodic dysmenorrhea is based on the fact that atropin diminishes the irritability of the autonomic nerve-endings in the uterus. In 1910, Drenkhahn[3] reported remarkable results from the injection of a solution of atropin directly into the cervical canal (1 mg. of atropin in 1 c.c. of water). If a speculum or syringe be *not* at hand, he advised the introduction of a tampon saturated with the atropin solution (1 per cent. strength). This plan of treatment Drenkhahn states he had followed for fifteen years, basing it originally on the experimental work of Schindler,[4] who showed that atropin has a direct action on the uterine muscle.

The method was taken up by Novak[5] of Vienna, who was struck by the fact that many women with increased irritability of the autonomic nerve system suffer with dysmenorrhea. In accordance with the *Krampftheorie* he suggested that the dysmenorrhea is due to the increased irritability of the autonomic nerve endings in the uterus. Novak administers the atropin in pills containing 0.5 mg. each, three being given each day, beginning just before the expected onset of menstruation. His preference for the administration of the drug by the mouth is a wise one, for the results appear to be just as satisfactory as by Drenkhahn's method, while he thus avoids the slight danger of infection associated with the latter. Novak's method is obviously less disagreeable, especially in the case of virgins.

Thirty-eight cases were reported by Novak, in thirty of which the results were distinctly favorable. All these patients had suffered with "crampy" pains, except one in whom the pain was rather continuous, and one in whom the character of the pain is not mentioned. In the thirty favorable cases the pain either disappeared entirely or else became insignificant. The less characteristic symptoms which so frequently accompany the spasmodic pain — backache, bearing down in lower abdomen, general lassitude, etc. — were not influenced by the atropin, which seemed to exert a special effect on the colicky pains. In one case the result was rather indefinite, the patient being better, but not strikingly so. In seven cases the treatment failed to relieve the pain. Among these seven were the two mentioned above as atypical, that is, not suffering with the spasmodic pains of typical "menstrual colic."

[5] Novak, J.: Zentralbl. f. Gynäk., 1911, xxxv, 576; Wien. klin. Wchnschr., 1913, xxvi, 2068.

EXPLANATION OF FAILURES

Novak is inclined to believe that failures, when they occur, are due to insufficient dosage. This would seem to be in conformity with the experimental work of Kehrer,[6] who found that in small doses atropin stimulates the uterine muscle, while in large doses it inhibits it.

Stolper, who has also employed the atropin method in a large number of cases, offers a different explanation for the failures which occur in a certain proportion of cases. He asserts that atropin is very efficient in those cases in which the dysmenorrhea is accompanied by other vagotonic symptoms. In a certain number of dysmenorrheics, however, vagotonic symptoms are absent, and, according to Stolper, there may even be symptoms indicating a heightened irritability of the sympathetic system (sympathicotony). As a means of clinical differentiation between these two groups, he lays much stress on a study of the blood-pressure. He lays down the rule that women with a normal or slightly raised blood-pressure react most promptly to atropin, while when the blood-pressure is greatly raised there is apt to be no response to the administration of atropin. The blood-pressure *must* be measured in the intermenstrual interval, not during menstruation or during the premenstrual period. Stolper, I may add, administers the drug either in suppositories (0.001 gm.) or by subcutaneous injection (0.00075 gm.).

PERSONAL EXPERIENCE

My own experience with the atropin treatment of spasmodic dysmenorrhea has been most encouraging. In the frequent cases of young unmarried women in whom pelvic examination is obviously undesirable, and who present the classic picture of spasmodic pain recurring with each menstruation, the atropin treatment is indicated without the preliminary of pelvic examination. In my own cases I have followed the plan of Novak, though I have frequently administered somewhat larger doses than those recommended by him. My experience has been that the cases which respond most favorably are, speaking generally, those in which the atropin has been pushed to the point of tolerance. The plan has been to commence the administration of the drug about two days before menstruation is expected to appear, and to continue its use until the second or third day of menstruation, depending on the usual duration of the pain. Patients differ, of course, in the degree of tolerance to the drug. Ordinarily, about 1/100 grain is given three times a day, unless some pain appears, in which event, if there are no symptoms of atropin saturation, the doses may be given somewhat more frequently. Many patients complain of dryness of the throat, itching of the skin, and sometimes even disturbed accommodation, in which case it may be necessary to lessen the dosage somewhat. When it is desired to study the effect of the atropin on dysmenorrhea, it is best to administer it alone, as in tablet form. In some cases, however, I have combined it with various other drugs of analgesic nature, such as aspirin. Further than the occasional symptoms due to overstepping of the patient's atropin tolerance, I have observed no bad results of any kind.

My purpose in writing this paper is to call attention to this method of treatment rather than to report my own results. My experience is still comparatively small, and since many of the cases are of very recent date it is scarcely suitable for detailed report. The results in the thirty or more cases of spasmodic dysmenorrhea which I have treated with atropin have been very encouraging—so much so as to impel me to further employment of the method. While there have been some failures, there have been, on the other hand, some strikingly successful results. For the failures I have no explanation to suggest other than those quoted above from Novak and Stolper. It is hardly necessary to add, *in conclusion*, that it would be illogical to expect good results from the administration of atropin in cases of dysmenorrhea — using the term in its broader sense — associated with definite pathologic lesions in the uterus or adnexa. In such cases the logical treatment of the menstrual pain is the removal or treatment of the causative lesion.

330 North Charles Street.

THE ENDOWMENT OF MOTHERHOOD*

JOHN F. MORAN, M.D.
WASHINGTON, D. C.

In this day, when the laity is discussing eugenics, and legislatures are enacting laws for the betterment of the race, it behooves us as medical men to consider the value of the potential mother and her unborn babe as a national asset and ascertain wherein their status can be benefited. The crux of the situation is the safety of the mother during pregnancy, labor and the puerperium.

The latest reports of the Bureau of Census on mortality statistics[1] show that slightly more than 42 per cent. of the infants dying under one year in the registration area in 1911 did not live to complete the first month of life, and that of these 42 per cent., almost seven-tenths died as the results of conditions existing before they were born, or of injury and accident at birth. Of those that lived less than one week about 83 per cent. died of such causes, and of the number that lived less than one day 94 per cent. died of these causes.

In the registration area of the United States, embracing 40.4 per cent. of the population, from 1901 to 1905, the yearly average puerperal mortality from all causes was 4,692, and in the five years ending 1910, with 48.9 to 58.3 per cent. of the population, the average death-rate was 7,219. If we divide the mortality into two groups: (1) accidents of childbirth, which includes deaths from abortion and miscarriages, placenta praevia, eclampsia, mania, *post-partum* hemorrhage and other accidents of pregnancy and labor including ectopic gestation, rupture of the uterus, adherent placenta and some cases of pelvic deformities, and (2) puerperal infection, we find that in the quinquennial period ending in 1905, the yearly average death-rate from puerperal infection was 2,057, or 44 per cent., and in the similar period ending in 1910 the average mortality from the same cause was 3,224, or 44.6 per cent.[2] In 1911, with 63.1 per cent. of the population in the registration area, the mortality from all causes incident to childbirth was 9,156, and of this, 4,376, or 47.7 per cent., were due to puerperal infection. In 1912, with 63.2 per cent. of the population in the registration area, the total death-rate was 9,035, and of this, 3,905, or 43.2 per cent., were due to puerperal infection. The minimum annual mortality from puerperal infection since 1900 was 39.7 per cent. (1906), and the maximum 47.8 per cent. (1911), while the general average was 44.8 per cent.

---

[6] Kehrer: Arch. f. Gynäk., 1907, lxxxi, 160.

* President's address, read at a meeting of the Washington Obstetrical and Gynecological Society.

[1] West: Pre-Natal Care, Children's Bureau, Dept. of Labor.

Since, in the last census (1912), not quite two-thirds of the population is represented in the registration area, and there occurred 9,035 deaths of mothers in childbirth, it is more than likely that if the entire country was registered, at least 15,000 if not more maternal deaths would be reported annually.

The figures published annually by the Registrar-General show that the mortality from puerperal infection in the British Isles has diminished in the last forty years and that in some parts of the kingdom there is evidence that up to a recent date the disease has shown a tendency to increased frequency. Lea[3] states that these facts constitute a grave reproach to the present-day practice of midwifery and are deserving of searching investigation. In five years, 1851 to 1856, the puerperal death-rate from all causes was 4.9 per thousand, and in the five years ending in 1906 it was still 4.2 per thousand. The mortality from puerperal infection varies between 2 and 2.5 per thousand. These figures do not include deaths from all causes dependent on or associated with pregnancy and the puerperal state. If these are added, the total mortality is raised to 5.09 per thousand.

The general septic mortality in Germany, according to the figures recorded by Von Herff, still amounts to 2 per thousand, although this shows a marked improvement on the figures of former years.

In the kingdom of Saxony the death-rate from infection from 1883 to 1886 amounted to 4 per thousand. In 1887 to 1894 it was 2.4 per thousand, and in 1901 to 1903 it was only 1.5 per thousand. The statistics from other parts of the German Empire show a reduction also, amounting in some districts to 50 per cent.

The puerperal mortality of Basle appears to be the lowest hitherto obtained; thus out of 10,497 births in three years, 1901-1903, the total deaths from puerperal infection amounted to 15, a mortality of 0.14 per cent. These figures afford a striking illustration of the success which follows the complete organization of the attendance on puerperal women, and the cooperation of nurses, medical men and the maternity hospital.

Why women at this day are permitted to entrust themselves to the hands of ignorant and untrained persons at the most important period of their lives would seem incredible but for the fact that it is actually true. It is not that we are more capable than our predecessors, for comparatively few epoch-making measures have been evolved in obstetrics in the last half century, but it is the immense advantage we possess in the added knowledge of asepsis and antisepsis and preventive medicine, owing to the developments in modern bacteriology.

It is more than three-quarters of a century ago since Holmes in his classical essay crystallized the prevailing views in support of the contagiousness of puerperal fever (infection), and the genius of Semmelweis illumined its etiology, and by his method of prevention of infection blazed the way for the development of the well-nigh perfect technic of to-day. It is over fifty years since that grand savant, Pasteur, established the correlation of germs with disease and proved that wound infection and puerperal infection were identical; and yet, notwithstanding these epoch-making advances of knowledge in the prevention of infection, the mortality and morbidity in parturition and the puerperium, in the general practice of obstetrics, has been but little diminished since the advent of the antiseptic era.

That thousands of women die every year from puerperal infection and accidents of childbirth, that many thousands more pass into the care of the gynecologists, and that one-third of the blindness in the world is the result of ophthalmia neonatorum are true and convincing proofs that obstetrics is wofully lacking in the careful study and attention it so rightly deserves.

How shall we lessen this frightful mortality and morbidity? To use a commercial phrase let us take stock and see wherein we can minimize the dangers that beset pregnancy, labor and the puerperium. While much of the etiology and pathology of the diseases of pregnancy are unknown, yet we have many measures of prevention at our command that lack universal application because of ignorance, carelessness and faulty judgment. The toxemias, ectopic pregnancy, pyelitis, hydatidiform degeneration of the chorion, placenta praevia, tumors, deformities of the pelvis and the various dystocias are, in the majority of instances, recognizable to the careful and painstaking physician.

Bacteriology has been of incalculable benefit in revealing the protean character of puerperal infection, and that it is mostly of external origin and due to ignorance or carelessness and, therefore, is largely preventable. Asepsis has made possible undreamed of achievements in surgery and obstetrics. The surgical and mechanical aspects of labor have during the last quarter of a century made great strides, and obstetricians have formulated definite principles governing the various complications that present themselves during the puerperal state.

The brilliant results of cesarean section, abdominal and vaginal, in contracted pelves, certain cases of placenta praevia and eclampsia, and in certain borderline cases that before the era of asepsis were deliverd by forceps or version, frequently resulting in the death of the child and mutilation of the mother, are now of such frequent occurrence that they excite little attention.

Symphyseotomy, and its recent variation, pubiotomy, are employed by some obstetricians in medium contractions of the pelvis, though as independent procedures they are being supplanted by the more advantageous cesarean section. They still have a limited field of application in impacted posterior face and cephalic cases and then usually as an adjuvant to forceps or version.

The induction of labor too, in contracted pelves, is yielding to cesarean section because of the increased likelihood of the survival of the infant. Yet, even with this abridgment, it has a large sphere of employment in the diseases that menace the life of the mother, as toxemias, placenta praevia, uncompensated heart lesions, some cases of tuberculosis, chorea, pernicious anemia and hydatidiform mole.

---

[2] Reports of Bureau of Census, U. S., 1900-1912.
[3] Lea: Puerperal Infection, London, 1910.

The forceps is the most valuable and most abused instrument in the obstetric armamentarium. When the indications for its employment are observed and application properly made, the chances of the child are increased and the suffering of the mother frequently shortened.

Version is one of the oldest and most serviceable of the obstetric procedures. When skilfully performed it is of great value in dissolving abnormal presentations, controlling hemorrhage in placenta praevia and securing immediate delivery.

Manual correction of defective rotation, and manual, bag and instrumental dilatation of the cervix are employed in suitable cases to promote and effect delivery.

Pituitary extract has proved to be of value in reinforcing flagging pains. Its intermittent action, simulating the normal action of the uterus, is of service in inertia. It should be administered only when there is no disproportion between the child and the pelvis and after the cervix is completely dilated. Neglect of these precautions may cause extensive lacerations of the cervix and even rupture of the uterus. It does not *initiate* labor pains but augments them.

The recent findings of Abderhalden, demonstrating the cleavage of placental proteins by ferments in the blood of the host during pregnancy, is a valuable addition to our knowledge of physiologic chemistry, and it is to be hoped that this line of investigation may solve the much vexed problem of toxemia and furnish an effective remedy against this terrible scourge.

Acidosis, when present in pregnancy, indicates toxemia and not nephritis unless a toxemia has been superadded. The urobilinogen test is of service in this connection in that a positive reaction is indicative of toxemia. It has long been observed clinically that pregnant women suffering with chronic nephritis rarely have eclampsia.

The long-cherished hope of a specific remedy for puerperal infection has not been realized. Serum and vaccine treatment have proved unavailing. Our principal reliance still must be in prevention, and when it is present, on general, supportive and surgical measures.

The importance of the supervision of pregnancy cannot be overestimated. Many abnormalities are detected by a painstaking examination during this period. Pelvimetry and palpation give valuable data not only of the size but also of the shape of the pelvis. Methodical urinalyses will detect toxemia and give timely warning of impending danger, while a carefully elicited history will furnish much important data concerning previous pregnancies and labors.

These are the principal resources, the judicious use of which, together with careful technic, enables the obstetrician, in hospital and private practice, to reduce the mortality and morbidity of parturition to the minimum.

The statistics of maternity hospitals afford the most striking evidence of the value of modern aseptic and antiseptic methods. In former years the death-rate in these institutions amounted to from 3 to 5 per cent. and at times to as much as from 8 to 10 per cent. At the present day severe infection has almost been entirely abolished, and the mortality has been reduced to a small fraction of 1 per cent. (from 0.1 to 0.2).

The figures of the York Road Lying-In Hospital,[3] during sixteen years, show that in 8,376 deliveries there were no deaths from infection.

In the Rotunda Hospital, Dublin, during the year 1907-1908, 2,060 women were confined without a fatality from infection arising in the hospital.

At the Clinique Baudeloque in Paris, in over 3,000 births occurring annually, the total mortality from infection during the last five years amounted to less than 0.09 per cent.[3]

In the Johns Hopkins Hospital, in the first 5,000 cases delivered, 2,750 being outdoor patients, the total mortality was fifty-five, a ratio of 1.1 per cent.[3] The death-rate from infection was 0.42 per cent., and of these patients at least one-half were infected before admission to the hospital.

In 9,090 patients cared for in the Columbia Hospital of Washington, D. C., from 1876 to 1912 the total mortality was 120, a ratio of 1.3 per cent. The death-rate from infection was 0.28 per cent. and of these twenty-six women, six were infected before admission.

Why is the standard of obstetrics in general practice so low? The following have been imputed to be the responsible agents: ignorance and indifference of the laity; that pregnancy and labor are normal processes and do not require experienced help; the midwife and her bargain counter inducement, and the laxity of the medical profession. While these are admittedly factors in the final analysis, lack of training of the medical graduate in practical obstetrics is the principal cause.

The results of Williams' questionnaire[4] on the midwifery problem in the United States showed that the present standard of teaching obstetrics, particularly clinically, is far from satisfactory. Many of the schools are inadequately equipped for the teaching of obstetrics properly, only one having an ideal clinic; many of the professors are poorly prepared for their duties and have little conception of the obligations of a professorship; many of the teachers admit that their students are not prepared to practice obstetrics on graduation; one-half of the answers state that ordinary practitioners lose proportionately as many women from puerperal infection as do midwives and that reform is urgently needed, and can be more readily accomplished by radical improvement in medical education than by the almost impossible task of improving midwives.

Surgery is made the intensive course of the curriculum to the disadvantage of general medicine and obstetrics, which are certainly of more vital importance to the recent graduate. More than 50 per cent. of the present-day graduates are aspiring to do surgery, and the number is increasing. Its spectacular aspect and the apparent ease with which the skilled surgeon does his work lure to disaster the unwary and untrained operator whose principal assets are the hemostat and self-assurance. The boon of anesthesia and asepsis has not been an unmixed blessing, for it has made possible the commission of innumerable tragedies under the guise of surgery. Those who have control of hospitals know that the average intern is so enamored of the knife that it is difficult to make him familiarize himself with laboratory and other nonsurgical duties. It is no great achievement to be able to do the mechanical part of surgery; any tyro with nerve can do that; but it is a fine accomplishment and a rare one, to be acquired only by experience, keen observation and sound judgment to think and act surgically. What is said of surgery applies with equal emphasis to operative obstetrics. Special aptitude and training are requisite for efficient work. Every obstetrician knows that a large share of his consultation practice is not so much to give counsel what to do but to correct an error of judgment or execution.

---

[4] Williams, J. Whitridge: Medical Education and the Midwife Problem in the United States, The Journal A. M. A., Jan. 6, 1912, p. 1.

Some will argue that the recent graduate is no more capable of taking care of a serious organic disease than to perform a surgical operation. While that may be true, the conditions surrounding each are apt to be different. The operator is often the sole arbiter as to his competency, while the physician, because of the nature of his work, which, as a rule, is subject to deliberation, can better safeguard the patient's interest. If the physician be incompetent or unsatisfactory a consultation or retirement from the case is likely to suggest itself. Surgery, on the other hand, frequently calls for prompt and decisive action, and if there has been an error of judgment or execution the injury done is often permanent.

* In the sense of conditions or operations dependent on pregnancy or labor, not "accidents" from external causes.
† Term not used in invidious sense.

A promising augury of the future of medicine is the advanced requirements for matriculation, the lengthened course and the elimination of the low grade colleges. The enforcement of the high standards of medical education and ethics should add to the proficiency of the profession, but they will by no means cure its most besetting evils, charlatanism and quackery. The more stringent the requirements for the legitimate practice of medicine are made the more certain is the harvest of the unscrupulous, who thrive on ignorance and credulity.

It is my firm conviction that the next move in the line of progressivism should be the revision of the curriculum. Surgery has been, in recent years, featured more and more at the expense of the other branches, particularly obstetrics. Surgical work is largely elective, requires special aptitude, a basic knowledge of anatomy, physiology, pathology, bacteriology and general medicine, and a discerning judgment which can be obtained only by a wide and varied experience under competent supervision. The graduate course in surgery, therefore, should be devoted to the study of its principles and diagnosis, while its practice should be regulated by postgraduate efficiency. Much of the time spent in the amphitheater could be more profitably devoted to the general and obstetric wards.

The most glaring default of medical teaching is the paucity of time and attention that is given to obstetrics. Its present standard is so low that it is a disgrace. To err from ignorance when human life and health are involved is lamentable, but when we possess the light and neglect to avail ourselves of the knowledge it is inexcusable, aye, often criminal. Yet we have known for several decades that puerperal infection is a preventable disease, and in spite of this fact quite 50 per cent. of the mortality in childbirth is due to this cause. What is needed then is for the colleges to take cognizance of the glaring omissions in the teaching of this important branch by providing ample facilities for the student actually to assist and attend patients during labor and also be instructed clinically in the supervision of pregnancy and the puerperium by competent teachers. A potent factor in much of the inferior and meddlesome midwifery practice owes its inception to the faulty and inadequate training of the student under the direction of an inexperienced intern, or his initiation in the outdoor confinement cases without proper supervision and facilities. No surgeon would elect to perform an operation except under the most favorable environment, and no obstetrician should permit his students to be trained in a haphazard and indifferent manner. Clinical obstetrics is the most exacting and onerous branch of medical teaching, and efficient service can be obtained only by a reasonable compensation.

The college curriculum should be revised so as to fit men to do the greatest good to the race. Obstetrics and general medicine should be intensively taught in the graduate course, and the practice of surgery and gynecology, which are largely elective, should be restricted to postgraduate teaching.

This is the era of specialism and rightly so, for the rapidly widening horizon of the science and art of medicine make it impossible for one mind to encompass the ever-broadening scope of its manifold developments and applications. It is likewise, however, an era of hysteria, distrust and commercialism. The profession of medicine is essentially philanthropic, but its history shows that many of its followers have ever been actuated by cupidity rather than by altruism. Surgery, like obstetrics, is suffering from incompetent and untrained operators and reform is urgently needed. The advanced standards of medical education and the ultimate standardization of the hospitals, together with the aid or control by the state, whose duty it is to conserve the health of its people, should greatly elevate the practice of medicine, obstetrics and surgery, but the morale of the profession will depend on its members recognizing their limitations and giving their best endeavors to the relief of suffering humanity.

Obstetrics is the most arduous, least appreciated, least supported, and least compensated of all the branches of medicine. Its dignity and importance will never be recognized as long as the incompetent female and male midwives with their bargain counter inducements are placed on an equality with the trained practitioner. That statistics may show that the results of the general profession are little if any better than those of the midwives is beside the question and proves that the standard of teaching of obstetrics is low, very low, and needs to be radically improved.

Recently the President of the United States issued a proclamation setting apart a day each year as a public expression of our love and reverence for the mothers of the country. It is fitting, then, that the medical profession should awaken to its sense of duty to the state and the family by inaugurating a nation-wide propaganda that shall have for its purpose the teaching of the laity that the long-cherished fallacy that pregnancy and labor are normal physiologic conditions and therefore require no special care, in the light of the clinical fact that normal pregnancy and parturition are the exception, must be abandoned, and that henceforth the proudest and noblest privilege of woman—motherhood—shall be zealously guarded and cared for by trained physicians and not by ignorant midwives, male or female.

The peroration of Oliver Wendell Holmes in his "Essay on the Contagiousness of Puerperal Fever" so beautifully expresses the duty of the physician to motherhood that I quote it *in extenso:*

> It is as a lesson rather than a reproach that I call up the memory of these irreparable errors and wrongs. No tongue can tell the heart-breaking calamity they have caused; they have closed the eyes just opened on a new world of love and happiness; they have bowed the strength of manhood into the dust; they have cast the helplessness of infancy into the stranger's arms, and bequeathed it, with less cruelty, the death of its dying parent. There is no tone deep enough for regret, and no voice loud enough for warning. The woman about to become a mother, or with her new-born infant on her bosom, should be the object of trembling care and sympathy wherever she bears her tender burden, or stretches her aching limbs. The very outcast of the streets has pity on her sister in degradation, when the seal of promised maternity is impressed on her. The remorseless vengeance of the law, brought on its vicitim by a machinery as sure as destiny, is arrested in its fall at a word which reveals her transient claim for mercy. The solemn prayer of the liturgy singles out her sorrows from the multiplied trials of life, to plead for her in the hour of peril. God forbid that any member of the profession to which she trusts her life, doubly precious at that eventful period, should hazard it negligently, unadvisedly, or selfishly.

2426 Pennsylvania Avenue, N. W.

Finding Fleas on Plague Rats.—The method of combing rats for fleas—particularly plague-infected rat fleas—presents certain disadvantages which have been obviated by the following method: From several tests it was found that fleas began to leave a killed rat as early as fifteen seconds after death and all had left the body a little more than two hours and fifteen minutes afterward. We therefore killed the rat by cephalotripsy and immediately placed the body on a glass-rod grating over a collection of water in a very large glass jar or the inverted cover of a garbage can; either one will answer the purpose. The fleas soon begin to leave the rat's body and drop into the water, and may be conveniently collected by means of a medicine dropper. We have obtained higher counts in this way than by chloroforming and combing or by any other method. C. F. Mason, *Rept. Dept. of Health*, Panama Canal.

THE AMINO-ACID CONTENT OF THE BLOOD AND SPINAL FLUID OF SYPHILITIC AND NON-SYPHILITIC INDIVIDUALS *

ARTHUR W. M. ELLIS, M.B.,
GLENN E. CULLEN, A.B., B.Ch.E.
AND
DONALD D. VAN SLYKE, Ph.D.
NEW YORK

Wide variations in the amino-acid content of the blood and spinal fluid of patients with syphilis have been reported. As these variations far exceeded any ever seen experimentally in animals even under most abnormal conditions, it seemed advisable to investigate the question. This communication reports the results of the quantitative determination of amino-acid nitrogen in the blood and spinal fluid of normal and syphilitic individuals.

In 1913, D. M. Kaplan,[1] and Kaplan and McClelland[2] described what they entitled "A Quantitative Chemical Reaction for the Control of Positive Wassermann Reactions." The reaction described was merely the quantitative estimation of amino-acid nitrogen according to the method of Van Slyke.[3] According to Kaplan and McClelland the amino-acid nitrogen of the blood is diminished in patients with syphilis, and the quantitative determination of amino-acid nitrogen in the blood may be used as a diagnostic procedure in doubtful cases. Kaplan[4] reports determinations of amino nitrogen in the blood of 109 patients. His results varied between 0 mg. and 15.716 mg. nitrogen per hundred c.c. of blood. Of the 109 patients fifty-one were clinically diagnosed syphilis, while fifty-eight were suffering from other pathologic conditions. In the patients showing clinical evidence of syphilis, the amino-acid nitrogen of the blood varied between 0 mg. and from 2.8 to 2.9 mg., and in the patients clinically negative between 4 and 15.7 mg. per hundred c.c. of serum. Kaplan[4] states that this difference in the amino-acid content of the blood may be used as a point in differential diagnosis. He says:

> If we should offer, for example, a patient whose serum resulted in a positive Wassermann reaction and who presented no physical or historical evidence of syphilis, and whose serum gave an amino content of over 4.0 mg. of amino nitrogen in 100 c.c. of serum, I would, on the strength of 472 corroborative analyses, exclude syphilis on that ground.

In a later paper Kaplan and McClelland[2] report the results of the determination of amino nitrogen in the blood of 229 patients. In this paper they report the amino nitrogen diminished, that is below 2.3 mg. per hundred c.c. in 90 per cent. of forty patients in whom syphilis was clinically present and the Wassermann reaction positive, and in 77 per cent. of thirty-two patients in whom syphilis was clinically present and the Wassermann reaction negative. They give also the results in 117 patients suffering from conditions other than syphilis; of these 117 patients only three showed more than 7 mg. amino nitrogen per hundred c.c. This is in striking contrast to the previous communication of Kaplan[4] in which forty-four out of fifty-eight gave results in excess of 7 mg. With regard to the determination of amino nitrogen in the spinal fluid Kaplan[4] says:

---

These results of Kaplan and of Kaplan and McClelland would appear to possess great theoretical interest and some practical importance. We have, therefore, considered them worth an attempt at confirmation. In this we have been entirely unsuccessful.

Our determinations were made with the usual technic as described by Van Slyke and Meyer[3] for the determination of amino-acids in blood. All determinations were made in duplicate. We have examined the blood in thirty-nine patients, in fifteen of whom a determination of the amino nitrogen in the spinal fluid was also made. The results are shown in Table 1.

It will be seen that in our series there was no such wide variation of the amino nitrogen in the blood (0 to 15.716) and spinal fluid (0.3 to 3.6) as that reported by Kaplan, and that in this series there was no evidence of any diminution of amino nitrogen in the blood of patients with syphilis. The cases have been divided into three groups: (1) non-syphilitic; (2) syphilis other than syphilis of the central nervous system, and (3) tabes, including one case of paresis. The average value for amino nitrogen for the three groups is almost identical, 6.06, 6.8 and 6.5. It will be seen that in this series the syphilitics show actually slightly higher results.

Observations of the amino nitrogen content of the blood and spinal fluid of the same patients at different times have also been made. The results are given in Table 2. The specimens of blood and spinal fluid were always obtained without allowing more than a few minutes to elapse between the two procedures. They may therefore be considered to represent the proportionate content of blood and spinal fluid at a given time. It will readily be seen that within certain limits the amino nitrogen content of both blood and spinal fluid varies at different times in the same individual and that such variations are of practically the same magnitude as those occurring between the different individuals in our series. It will be seen also (Table 2) not only that the absolute amounts of amino nitrogen in blood and spinal fluid vary, but also that the relative amounts of these show a wide variation, in one individual the proportion of spinal fluid amino nitrogen to blood amino nitrogen being at one time 0.75, while two weeks later it was only 0.40, the absolute amount in the blood being practically the same on the two occasions.

TABLE 2.—AMINO NITROGEN CONTENT OF BLOOD AND SPINAL FLUID AT DIFFERENT TIMES

Case No.	Diagnosis	Date	NH_2 Nitrogen in mg. per 100 c.c. Blood	NH_2 Nitrogen in mg. per 100 c.c. Spinal Fluid	Ratio of Spinal Fluid NH_2 Nitrogen to Blood NH_2 Nitrogen	Wassermann Reaction Blood	Wassermann Reaction Spinal Fluid c.c.
1701	Tabes	3/ 3/14	8.3	3.6	0.44	+±	0.8++

		3/17/14	8.1	4.1	0.45	++	0.4++
		4/ 3/14	5.9	4.5	0.75	++	0.4++
		4/17/14	5.8	2.3	0.40	++	0.6++
1794	Tabes	2/27/14	7.6	2.7	0.36	++	1.0++
		3/27/14	6.9	2.0	0.29	++	0.8++
1111	Tabes	3/ 3/14	6.0	2.5	0.42	—	2.0++
		3/17/14	6.6	3.1	0.47	—	2.0++
1098	Tabes	2/26/14	7.5	2.5	0.29	—	0.6++
		4/ 3/14	8.2	2.6	0.32	—	1.0++
Average			7.1	3.0	0.42		

Both tables show very clearly that absolutely no relation exists between the amino nitrogen content of the blood or spinal fluid and the Wassermann reaction.

CONCLUSIONS

1. The amino-acid nitrogen of the blood varies within certain definite limits (4.5 to 8.5 mg. per hundred c.c.) in different individuals.

2. A similar variation occurs in the same individual at different times.

3. The amino-acid nitrogen in the spinal fluid in different individuals, and also in the same individuals at different times, varies between approximately 2 and 4 mg. per hundred c.c.

4. The amino-acid nitrogen content of the blood in syphilitics varies within exactly the same limits as in the blood of non-syphilitics. The amino-acid nitrogen content of neither the blood nor spinal fluid of a syphilitic bears any relation to the Wassermann reaction.

5. The conclusion of Kaplan and of Kaplan and McClelland that in patients with syphilis the amino-acid nitrogen of the blood is diminished, and that such determinations may be used as a means of diagnosis, is incorrect.

THE EFFECTS OF COLLARGOL AS EMPLOYED IN PYELOGRAPHY

AN EXPERIMENTAL STUDY*

DANIEL N. EISENDRATH, A.B., M.D.
CHICAGO

Prompted by the report of a number of cases of ill effects, even death, following the injection of collargol into the renal pelvis for roentgenographic purposes, I became interested in the question of whether or not collargol can damage the kidney and can cause death when so injected. With the assistance of Dr. E. W. Schnoor and Miss Elizabeth Byrne, we have attempted to study the question from every angle, employing dogs and measuring the pressure with which the fluid was injected. With the exception of some experiments on pigs' kidneys (removed from the body), reported by Whitman,[1] we are the first to study the question by not only measuring the amount injected, but also observing the effects of varying this quantity, as well as the pressure with which it is injected.

We believe that we are able to show from the lesions found in our experiments on healthy and diseased kidneys injected with various substances (collargol, cargentos and methylene blue) that the majority of the ill effects[2] reported up to the present time have been due to lack of consideration of the fact that when the capacity of the human renal pelvis is exceeded by the amount of fluid injected, and a high degree of pressure employed, the solution is either forced into the loose tissues around the renal pelvis and kidney, or into the renal parenchyma, and from here into the circulation and deposited in various viscera.

TECHNIC

Dogs were employed in all of the experiments. Under ether anesthesia and all aseptic precautions the bladder was opened and a ureteral catheter, which could be boiled, inserted through the vesical orifice of the ureter to be injected, until one could see the location of the eye of the catheter through the intact wall of the ureter above the bladder, in order to watch the first escape of fluid from the catheter. We could thus closely observe the quantity injected into the renal pelvis, and the pressure employed. A mercury manometer, inserted into the column of the solution injected, enabled us to note the slightest fluctuations in pressure. After the fluid had been injected, the catheter was withdrawn and the bladder incision sutured. We were able to imitate perfectly the method of using collargol in the human being. Only one animal out of a total of forty showed evidences of infection, so that we can eliminate this as a factor in interpreting our results. In Experiment 316, as well as in the experimental hydronephrotic and infected kidneys, the solutions were injected directly into the proximal end of the ureter.

PLAN OF THE EXPERIMENTS

The average capacity of the renal pelvis of the dog is from 2 to 2.5 c.c. We thought that by filling the renal pelvis with this amount, or one slightly above it, we could best imitate the gravity method which is correctly held to be least dangerous in the human being. We found that when a buret filled with collargol was raised to a level of 3½ feet above the operating table, the fluid escaped under a pressure of 29 mm. Our first series corresponds to the average gravity injection, as given daily. In the second series the quantity and pressure were increased moderately, and in the third series both were increased considerably, in order to ascertain as closely as possible how much pressure, and the amount of excess in fluid beyond that of the ordinary capacity of the renal pelvis, would be required to force the solutions into the kidney and its vessels. We killed the animals at different periods after the injection, in order to study the question of permanent injury to the kidney and other viscera. In addition to collargol in 10 and 20 per cent. solution, we undertook experiments with cargentos, a salt containing 50 per cent. silver, and also with methylene blue. In our earlier experiments only the injected kidney was examined. It was not known at that time that the collargol entered the blood-current when too much pressure or too large a quantity was employed, since our article[3] of May 2, 1914, was the first publication to describe such an occurrence.[4]

The first series shows that the injection of collargol under a pressure not to exceed 30 mm. will fill the renal pelvis. Only a minimal amount of the collargol enters the kidney parenchyma or infiltrates the peripelvic tissue. An elevation of 3½ feet of a column of fluid causes it to flow at a pressure of 29 mm.; hence this first series proves that the gravity method is the safest one to employ in injecting any solution into the renal pelvis.

[4] At the time Experiments 304 and 310 were performed, we had not read the article by Rehn, Jr. (Centralbl. f. Chir., 1914, No. 4), in which he simply mentions the fact that he found collargol in other viscera, but does not give any details and has not published them up to the present time.

SUMMARY OF EXPERIMENTS

Series 1.—Ten per cent. collargol injected under low pressure.

There were six experiments in this series, the quantity injected varying from 2.25 to 3 c.c., that is, just equal or slightly beyond the capacity of the renal pelvis. A distinct resistance was felt when 3 c.c. had been injected, showing that no more collargol could be safely introduced into the renal pelvis. The pressure under which the collargol was injected varied from 13 to 32 mm. The first dog was killed immediately and the other five 24, 48, 72, 96 and 144 hours, respectively, after the injection. The only three findings of value were in the following three experiments:

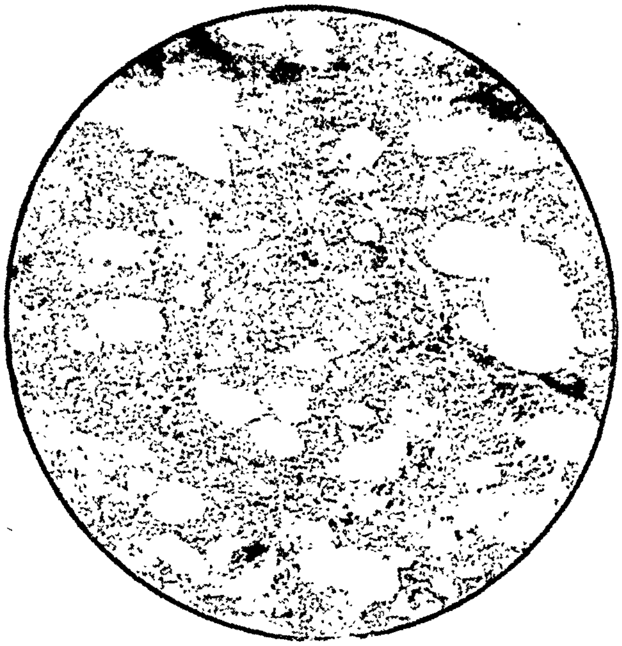

Fig. 6.—Lung from Experiment 327, showing hemorrhagic infarct around collargol.

Experiment 302: 2.75 c.c. at 13 mm. Killed immediately. Small amount of collargol in the interstitial tissue of medulla of kidney.

Experiment 306: 3 c.c. at 20 mm. Killed after 24 hours. Slight peripelvic collargol deposits.

Experiment 332: 2.4 c.c. at 32 mm. Killed 144 hours after injection. Kidney showed marked inflammatory reaction in medulla of kidney, and evidences of slight hemorrhages into lungs and spleen. Hemorrhages into the interstitial tissue of the kidney and into the glomeruli were found so constantly, even when sterile water was injected, that they were thought to be due to trauma rather than to the collargol.

Series 2.—Ten per cent. collargol injected under moderate pressure (30 to 70 mm.).

Experiment 313: 4 c.c. at 50 mm. Killed 24 hours later. Small amount of collargol in interlobular septa of lungs.

Experiment 314: 5.5 c.c. at 45 mm. Killed 48 hours later. Small amount of collargol in interstitial tissue and in blood-vessels of the injected kidney.

Experiment 322: 3 c.c. at 45 mm. Killed 96 hours later. Hemorrhages into renal parenchyma more marked than usual.

Experiment 319: 5 c.c. at 50 mm. Killed 144 hours later. Small amount of collargol in interstitial tissue of the kidney; also present in small amount in lungs and liver.

Experiment 317: 5 c.c. at 52 mm. Killed 20 days later. Small amount of collargol in the kidney, undergoing resorption, and in vicinity of this collargol there are evidences of intense inflammatory reaction. Small amount of collargol in the interlobular septa of lungs. Subcapsular and parenchymatous hemorrhages in spleen.

Experiment 312: 4 c.c. at 47 mm. Killed 30 days later. No collargol found, but injected kidney showed intense inflammatory reaction in the cortex.

COMMENTS ON SECOND SERIES

In Experiment 313, in which the capacity of the renal pelvis was slightly exceeded (4 c.c. at 50 mm. pressure), there was a small amount of collargol deposited in the lungs. In 314 (5 c.c. at 45 mm.), collargol was found both between the tubules and in the blood-vessels of the kidney. In 322, there were evidences of intense inflammatory reaction when the animal was killed 96 hours later. The same is true in 317, in which animal was killed 20 days after injection, as well as in 312, killed 30 days after injection. Evidently the deposits of collargol caused an intense inflammatory reaction, as the result of the presence in the tissues of a foreign substance. In 319, the collargol was forced into the renal blood-vessels and was deposited in small amount in the lungs and liver. In 317, there was collargol in the lungs and evidences of hemorrhages in the spleen.

Series 3.—Ten per cent. collargol injected under high pressure (70 to 140 mm. Hg).

Experiments 304 and 310 were reported May 2, 1914, as a preliminary communication.[4]

Experiment 304: 20 c.c. at 100 mm. pressure. Dog died five minutes after injection was begun. Injected kidney showed many black areas which proved to be collargol lying both within the tubules and in spaces between the tubules, which were of traumatic origin (Fig. 1). Lungs were of a deep black, and sections taken from all lobes showed numerous capillary and larger vessels filled (Fig. 2) with the collargol in the form of emboli. The liver and spleen both contained much collargol. The surface of the liver (Fig. 3) had many yellowish-brown nodules, due to collargol deposits or infarcts and the collargol was found within the lumen of many hepatic vessels (Fig. 4). The spleen and lungs showed in addition to the collargol, many hemorrhages.

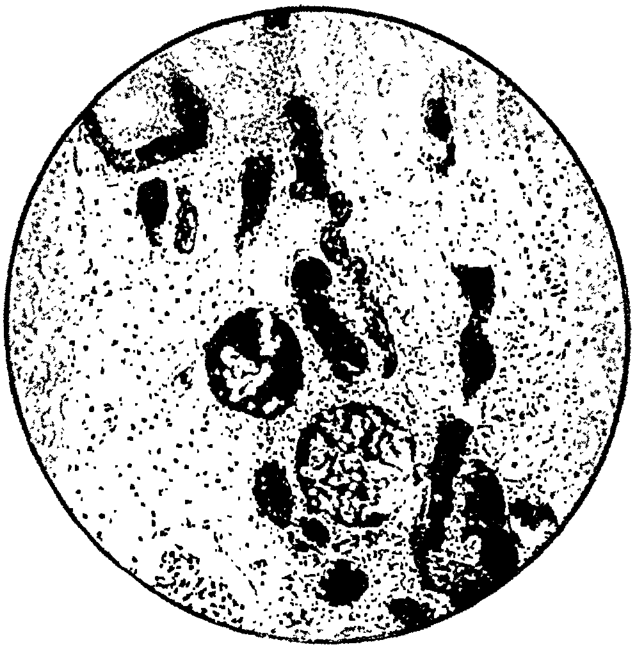

Fig. 9.—Kidney from Experiment 329; tubules and glomeruli filled with 20 per cent. collargol.

Experiment 310: 30 c.c. at 100 mm. pressure. Animal died thirty minutes later. There were a number of collargol infarcts in the injected kidney and the microscopic appearance was the same as in 304. The lungs showed much less collargol than in 304, but there was an extensive edema of the lower lobes. The liver and spleen showed evidences of hemorrhages, but contained less collargol than in 304. This was due to the fact that much of the collargol had escaped into the tissues around the renal pelvis, and thus less entered the circulation than in 304. Death was undoubtedly due in this dog to the acute pulmonary edema, whereas in 304 it was the direct result of so many capillaries being filled by the collargol emboli.

In Experiment 316 the collargol was injected directly into the proximal ends of both ureters, in order to observe the rise in pressure as the quantity injected was increased. The pressure when 5 c.c. had been injected was 48 mm., and rose gradually until it was 98 mm., when 10 c.c. (four times the capacity of the renal pelvis) had been injected. Both kidneys showed the typical collargol deposits and infarcts. In other experiments of this series, in 303 (7 c.c. at 80 mm.) the kidney showed a typical collargol infarct when the organ was removed fifteen minutes later. In 321 (6 c.c. at 94 mm.) the dog died seven days after the injection. The lungs showed extensive ecchymoses on the pleura and pneumonia in the stage of red hepatization in several lobes. The close proximity of a number of particles of collargol to the pneumonic areas (Fig. 5) justifies, we believe, the conclusion that the collargol played an important part in the etiology. In one section the collargol is seen to be adherent to the intima of a vessel close to a pneumonic area. In 310, in which the pulmonary edema was the cause of death, the collargol was, we believe, an irritant. In 327 (Fig. 6) the lung showed numerous hemorrhagic infarcts directly around the collargol deposits in the lung. From the constancy of our findings, there can be no doubt of the direct causal relation of the collargol to all of the acute pulmonary changes.

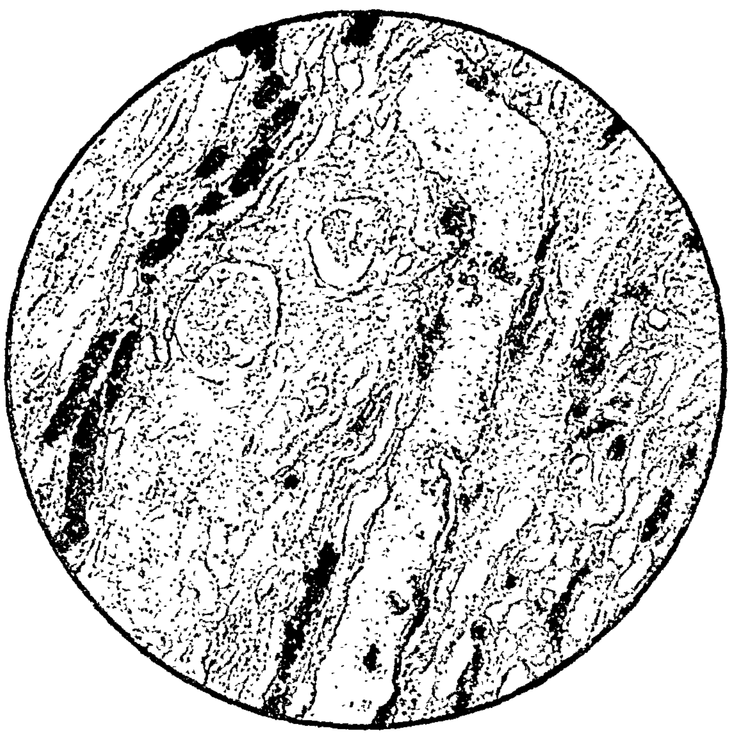

Fig. 10.—Kidney from Experiment 329, showing collargol breaking into vessel.

Experiment 336: Injection of 20 c.c., 10 per cent. collargol directly into the iliac vein. This experiment was to determine whether a substance like collargol would cause death, as in 304, when injected directly into the systemic circulation. The dog died in four minutes; respiration stopped before the heart did. The lungs presented almost the same appearance as in 304, and also a large hemorrhagic infarct. All of the viscera and the blood in the vessels contained the collargol. Sections taken from the lungs showed innumerable blood-vessels (Fig. 7) filled with collargol emboli, as in 304. The vessels of the liver were also filled with the collargol (Fig. 8). This experiment corroborates our 304, showing that death can be caused by the collargol obstructing so many pulmonary capillaries that respiration is impossible.

The occasional clinical use of stronger solutions of collargol led us to inject 20 per cent. collargol in Dog 329. The results were the same as when the weaker solution was employed. The animal died twenty-four hours after 37 c.c. had been injected at 140 mm. pressure. The tubules and glomeruli were filled to an even higher degree (Fig. 9) than in Series 3. In one of the sections the collargol could be seen entering the vessel and lying within it (Fig. 10). Death was due to acute pulmonary edema, and there was much collargol in the interlobular septa, as well as in the liver and spleen.

Series 4.—Cargentos used instead of collargol.

To see how other silver salts which have been recommended as substitutes for collargol would act, we injected cargentos, which contains 50 per cent. silver, into three dogs. In Experiment 326 the animal died twenty-four hours after 17 c.c. of a 10 per cent. solution had been injected at 140 mm. The tubular deposits and large infarcts (Fig. 11) appeared in the same manner as with collargol, and in addition there was a marked inflammatory reaction. The spleen, liver and lungs showed many hemorrhagic areas, and there was a well-marked pneumonia. In Experiment 334 the dog died on the fourth day after 6 c.c. of a 25 per cent. solution had been injected at 80 mm. The pneumonic changes were even more advanced than in 326. In 333 the dog died twenty minutes after 14 c.c. of 25 per cent. cargentos had been injected at 100 mm. In addition to the cargentos forming perfect casts of the urinary tubules (Fig. 12), the lungs contained much of the cargentos.

Series 5.—Collargol injected into kidneys in which experimental hydronephrosis and infection had been produced.

Experiment 327: 20 c.c. of 10 per cent. collargol at 196 mm. injected into ureter of hydronephrotic kidney of three weeks' duration. Animal died in ten minutes. There was a large hemorrhagic infarct in the lungs, and in sections much collargol was found in the lungs, especially near the infarct (Fig. 13). The kidney showed a few collargol streaks, but sections revealed the fact that the tubules and interstitial tissue had resisted the entrance of collargol far better than a nonhydronephrotic kidney. There was comparatively little collargol in the tubules or between them. In Experiment 331 an experimental hydronephrosis and ascending infection had followed implantation of the ureter into the bowel, and injecting its proximal end eighteen days later with 40 c.c. of 10 per cent. collargol at 140 mm. pressure. Animal died twenty-four hours later. Here, again, the kidney resisted the collargol better than a normal one, and the parenchyma contained only a relatively small amount of the fluid (Fig. 13). There were many hemorrhagic infarcts in the lung and pneumonic areas. There was a little collargol in the lungs, liver and spleen.

Series 6.—Methylene blue used instead of collargol.

We thought that neutral substances like 10 per cent. methylene blue might cause the same changes and verified this by injecting it in the same quantities and at similar pressures as were used with collargol and cargentos. The animals died within from five to twenty minutes, and the hemorrhagic infarcts and embolic plugging of the pulmonary vessels resembled in every way those observed with the silver salts.

COMMENTS ON EXPERIMENTS

In Series 1, in which the amount of collargol injected did not exceed the capacity of the renal pelvis, and only enough pressure was used to distend it lightly, practically no deposits in the kidney occurred, and no damage to its epithelium. When the pressure and quantity were increased, as in Series 2, the collargol was found more constantly, either in the kidney or lungs, or both. In 314 it was found in the blood-vessels of the kidney. In animals which lived for some days there was ample evidence that some irritant had been present, and had been the cause of an intense inflammatory reaction. The more severe effects which collargol and cargentos can cause in both normal and pathologic kidneys are well shown in the remainder of the experiments. There can be no doubt that when more fluid is injected than the renal pelvis can hold, or it is injected with too much force, then the tension within the renal pelvis rises to such an extent that the fluid, whether it be collargol, cargentos or methylene blue, or any other substance sufficiently concentrated, is forced into the interstitial tissue and tubules, and soon breaks into blood-vessels and is carried by the veins to the lungs, and produces either embolism with immediate death, or an acute pulmonary edema, hemorrhagic infarct or a pneumonia. The photomicrograph shown in Figure 12 illustrates how the collargol is forced into the vessels and carried to distant parts. If carried to the liver, spleen, brain and other organs, the collargol is either deposited in the parenchyma or causes infarcts or hemorrhages.

The experimental work of Strassman and Wossidlo will be discussed in detail when this paper is published in full. Rehn's investigations have been published only in a preliminary form. The experiments of these three surgeons were all performed without taking into consideration the question of the pressure with which the fluid was injected. This, as we have attempted to show, is the key to the entire question. In other words, *collargol will not injure either the healthy or diseased kidney if care be taken not to inject more than the renal pelvis can hold.* If this limit is exceeded, or the fluid injected with too much force, serious results may follow, such as (*a*) larger (infarcts) or smaller deposits in the kidney and perirenal or perinephritic tissue; (*b*) infarcts or deposits or hemorrhages into the spleen and liver, and (*c*) various lung changes, such as embolic plugging of the vessels, hemorrhagic infarcts, acute pulmonary edema or pneumonia.

The use of collargol and cargentos in pyelography does not deserve to be condemned. They are perfectly safe aids to a most valuable method of diagnosis, when employed with care. Our experiments clearly show the dangers of injecting any fluid, even concentrated methylene blue, into the renal pelvis when too great a quantity and too much pressure are employed.

30 North Michigan Avenue.

ABSTRACT OF DISCUSSION

Dr. W. F. Braasch, Rochester, Minn.: Dr. Eisendrath has certainly shown conclusively that collargol or any other solution of colloidal silver, when injected with pressure, can destroy the kidney tissues. In some two thousand clinical cases in which we have employed pyelography, I am not aware of having caused any damage to the kidney by means of overdistention. Any possibility of such danger is obviated by the gravity method. As Dr. Eisendrath has emphasized, if one does not use too much pressure there is no reason why any trauma or destruction of the kidney tissue should follow the injection of the solution. It has been my experience, however, that we do have trouble in certain cases when the injected silver is not drained out afterward. I have seen necrosis in four cases of hydronephrosis in which the collargol did not drain and the contraction of the pelvis forced the collargol up into the tubules and caused focal necrosis. All of these kidneys were primarily surgical, and their removal would probably have been necessary. Undoubtedly this is a source of danger. Therefore, we should take care not to inject in any case of hydronephrosis in which the injected solution cannot drain afterward and whenever the diagnosis can be made without a pyelogram. In following out a series of experiments on dogs along this line recently, Dr. Mann and I have injected different preparations of colloidal silver into the pelvis and ligated the ureter a short distance below. We found that focal necrosis will result in the parenchyma in practically every case. The various colloidal preparations all act in about the same way. In search for a harmless substance we also employed an emulsion of silver iodid, 5 per cent., and in seven dogs injected with this we found no evidence of focal necrosis. The great objection to silver-iodid emulsion, however, is that it has to be used with a syringe, since it is too viscid to employ by the gravity method. Pyelography is not to be employed with impunity, and should be used only in selected cases. Its use is only excused when the diagnosis cannot be made without it. If we carefully select our cases, and do not use colloidal silver in conditions in which it cannot drain after injection, and if we use the proper technic, there is no reason why an experienced cystoscopist should have serious consequences from pyelography. I believe, however, that we should continue our search for a harmless preparation which could be employed more generally.

Dr. A. J. Crowell, Charlotte, N. C.: I was glad to hear Dr. Braasch say that we ought to search still further for a drug that would be less harmful to the kidney in pyelography. I disagree with Dr. Eisendrath that silver or collargol is not dangerous. I had, about two months ago, the misfortune to lose a patient on whom I used collargol. The patient was referred to me for a roentgenogram and then for ureteral catheterization and collargol injection for diagnosis. When the patient was admitted to the hospital a picture was immediately taken for kidney stone, which proved to be negative. This patient gave kidney symptoms. The ureters were catheterized. The urine coming from the right ureter was perfectly clear and came away intermittently. That from the left was continuous and cloudy, which condition was afterward proved to be caused by pus, and a few tube casts were found, both hyaline and granular. The catheter in the right ureter was removed after it had remained for two or three minutes. About 3 ounces of urine had been withdrawn from the left kidney—in fact, the catheter was left in until the urine came away intermittently. I estimate that at least 1½ ounces of urine was secreted during this time. Therefore, I had no hesitancy in injecting into the pelvis of that kidney 12 c.c. of a 10 per cent. solution. This was injected with a syringe, but very slowly, and on the first indication of discomfort the patient was instructed to notify us, which she did, and the picture was taken immediately. The catheter was left in for ten minutes at least, for two reasons: first, to allow the collargol to return, which it did very readily; secondly, to allow the time for the development of the roentgenogram. The picture was reported all right, the catheter was removed, but the patient suffered such excruciating pain that it became necessary at once to give a hypodermatic of morphin. She was taken care of as best we could by various remedies for the relief of the pain and to overcome shock. She remained a very sick woman until the fifth day when she died. There was almost complete suppression of urine from the very beginning. The greatest quantity of urine secured as ascertained by catheterization in any twenty-four hours was 3 ounces. I was unable to secure a complete post-mortem, but obtained the kidneys. Finding collargol in the opposite kidney of this patient, suggested trying experimental work on dogs to ascertain the distribution of the drug. I injected 10 c.c. into the pelvis of the right kidney of one dog and 5 c.c. into the right kidney of another. I injected 10 c.c. into the kidney pelvis of one and it died in five minutes. The other we killed in two days. We found collargol in the lungs, kidney, liver, spleen and muscles of the heart. I have no specimens of the patient who died, save from her kidneys, but why she should die from suppression of urine when only one kidney was injected is a question. Post-mortem examination showed the capacity of the woman's kidney to be 1½ ounces. I injected only 12 c.c. of the solution, so it was not full. On the second or third day after the injection she developed symptoms of purpura. Even where she was given hypodermatic injections, there was an extravasation of blood under the skin. She suffered considerable hemorrhage from the mouth and bowels after the second or third day.

Dr. F. R. Hagner, Washington: I saw in consultation a case in which a 25 per cent. argyrol solution had been used. This was done by Dr. G. Brown Miller of Washington, an able gynecologist. He assured me that he put in less than 8 c.c. of argyrol. This woman was about 70 years of age and was supposed to have a tumor of the kidney. Immediately after the injection she complained of discomfort and pain in the precordial region. For twenty-four hours she had practically complete suppression of urine. In the next twenty-four hours she excreted approximately 16 ounces. About the third day she began to pass blood by the bowel, her stomach became very much distended, a stomach-tube was passed and her stomach was found filled with blood. She had hemorrhages from the gums, nose, and blood in the urine and petechial hemorrhages over the entire body. When I saw her I suspected she might have mercuric chlorid poisoning. It looked like a case of metallic poisoning. Has any one seen any symptoms of metallic poisoning in any of these cases in which the colloidal silver salts have been used? We were unable to get a necropsy in this case.

Dr. H. D. Furniss, New York: I had a patient who gave much the same history as the patient reported by Dr. Hagner. She was injected with collargol, and within a few minutes she had an immense amount of pain. Following that the condition cleared up, but on the third day I explored the left kidney and found an anomalous blood-vessel running to the lower pole. Three days after the operation and five days after the injection the patient had suppression of urine, which lasted for eight days, and during that time there was no more than 1 ounce excreted in any one day. At the end of that time I decapsulated the right kidney. I was afraid of getting too much hemorrhage from the side I had previously operated on. Within twenty-four hours after the decapsulation urine began to be excreted, and was excreted in fairly good amount for the next four days, at the end of which time she died; but after the operation this patient had hemorrhages from the nose and mouth, just as Dr. Hagner has reported. Collargol is sometimes used therapeutically intravenously, in a percentage which is a solution. In these cases in which it is injected into the kidney it is in the form of an emulsion, and it has struck me that that probably accounts for the emboli that are found.

Dr. Martin Krotoszyner, San Francisco: I made an observation similar to that of Dr. Hagner in a woman of about 40, who after injection of a small amount of a 20 per cent. cargentos solution developed symptoms similar to those described by Roessle, and which this author considered to be due to an acute silver toxemia or argyria. I cannot share Dr. Eisendrath's optimism regarding the avoidance of all dangers connected with pyelography by regulating the pressure in injecting the silver salt. Shortly before leaving home I injected in a man of 45, with a unilateral pyuria of doubtful character, under very low pressure, 2 or 3 c.c. of a 10 per cent. collargol solution. In spite of the utmost precaution in the procedure and in spite of discontinuing the injection at the first sign of discomfort on the part of the patient, the exposed kidney presented a focus on its capsule which was proved by the pathologist to be due to penetration of collargol through the renal tubules. This observation and similar ones recorded in the literature by others prove that the last word on the cause of pyelographic mishaps is not yet spoken. It is to be hoped, though, that the dangers of pyelography will be avoidable so that this important diagnostic method, which we would not like to dispense with in our armamentarium, will not become entirely discredited.

Dr. Frederick R. Charlton, Indianapolis: I report a death from collargol. This patient had a tumor mass (necropsy was not obtained) perhaps the size of a small grapefruit, supposedly hydronephrotic. This was a year ago, before the danger of using a piston syringe was so fully understood. We injected 15 c.c. of a 25 per cent. collargol solution. Before the injection was completed the patient was complaining of distress. I waited for a moment until he was easier, and then continued the injection until I had injected the full 15 c.c. I labored under the impression at that time that perhaps it would be somewhat difficult to get a dangerous pressure from that amount of fluid, feeling that a certain percentage of it would find its way backward down the course of the ureter along the catheter. That belief does not seem to be borne out by later experiences. We took our roentgenogram, getting an excellent one, showing extravasations of collargol well out toward the cortex and outlining a large mass of some kind. Our patient went into collapse and died in eight hours. This man had walked into the Roentgen-ray laboratory, so that the case was a distressing one, and we could not get a necropsy for obvious reasons. I felt at the time that perhaps it was due more to cardiac collapse than anything else. Granting that I had produced some small rupture in the pelvis, I could not see why that should cause immediate death. I did not feel at the time that collargol was to be regarded as dangerous from the point of view of its drug properties. And so in trying to explain my patient's death I felt that perhaps we had a bad myocardium, that I had produced just enough pain to cause considerable shock, and that his heart had not been able to rally after such shock.

FRACTURES OF THE INFERIOR MAXILLA

A REPORT OF 1,065 CASES TREATED*

HENRY S. DUNNING, M.D., D.D.S.
NEW YORK

During the last eight years I have had quite an opportunity of studying fractures of the maxillary bones at the New York College of Dentistry. At the college we have a large daily oral surgery clinic under the direction of Prof. Faneuil D. Weisse and myself, which is fed by the outpatient department of nearly all of the large hospitals of Manhattan. Since the founding of the oral surgery clinic at the college in 1906, we have treated over 1,200 fractures of the inferior maxillary bone, but I am sorry to say that at this time I can present figures taken from only 1,065 cases, as some of the records are not very complete.

Stimson says, "By fracture, in the surgical sense, is meant the breaking of a bone or cartilage." The liability of a bone to fracture depends on its shape, size and degree of exposure to external violence or trauma, and also to its exposure to extreme muscular action. On account of its peculiar horseshoe shape, its prominence and its unsupported position, and the fact that it is somewhat weakened by the carrying of teeth that often become diseased, the inferior maxillary bone is the most frequently fractured bone of the face.

Stimson shows that in 14,566 fractures of all the bones of the body treated at the Hudson Street Hospital (1894-1905), 502 of these were fractures of the inferior maxilla. From his figures this bone is the tenth on the list as being most often fractured. Another reason for its frequency to fracture is its weakened condition because of physiologic absorption after teeth are extracted. Most fractures of the body of the bone proper, or of the rami, are complete fractures, and it is the complete fractures that will be discussed to-day.

* Because of lack of space this article is abbreviated in The Journal. The complete article appears in the Transactions of the Section and in the author's reprints.

TABLE 1.—INJURY AND CAUSES IN 1,065 CASES OF FRACTURE OF THE INFERIOR MAXILLA*

Injury and Causes	No.	Per Cent.
Blow of fist	495	46.5
Run over by wagon	38	3.5
Elevator	14	1.5
Gunshot	5	0.5
Pathologic fracture	2	0.2
Extraction of teeth	5	0.5
Edentulous mouths	10	1
Miscellaneous	238	21
Kicks	45	4
Fall	140	13
Baseball bat	13	1.5
Club	32	3
Thrown ball	7	0.6
Railroad accidents	2	0.2
Blackjack	17	1.6
Cranking machines	3	0.2
AGE		
From 1 to 10	68	6⅓
From 10 to 20	93	8.5
From 20 to 30	298	28
From 30 to 40	340	32
From 40 to 50	184	17
From 50 to 70	82	7.5
SEX		
Male	992	93
Female	73	7

* This and the following table comprise a report of 1,065 cases of fracture of the inferior maxilla treated at the New York College of Dentistry during the years 1906-1913, taken from the service of Faneuil D. Weisse, dean and professor of oral surgery, anatomy and surgical pathology.

The fracture of the alveolar process is very numerous and occurs often on the extraction of a tooth. Complete fractures of the body of the bone are generally vertical in direction, and about 98 per cent. of these fractures are compounded to the mouth, when there are teeth present. This is due to the fact that most of the fractures of the body of the bone occur at the alveolus of a tooth, and runs along the tooth cavity to its end, and then enters the body of the bone in the same direction. The fracture of this bone is the most often compound fracture of any in the body, owing to its thin covering of gum tissue and mucous membrane, and of course, for this reason, it is the most often infected fracture. It is not often compounded to the face. The vertical direction is also due to the fact that the bone is most often fractured by a blow that bends the bone at right angles to its long axis. A blow on one side of the jaw will sometimes cause a fracture on the opposite side in the same way that a blow on a barrel hoop will be felt at a point opposite the point where the blow is received. This is called "fracture by *contre coup*."

In edentulous mouths the fractures are usually simple ones, and are not so apt to be vertical as there is no tooth cavity to weaken the bone, and to direct the line of fracture. These often become compound fractures, as the gum is so thin that pressure of an interdental splint often causes a sharp edge of bone to penetrate the soft tissue.

Fractures of the alveolar process are usually in the anterior part of the jaw, where they are more exposed to trauma.

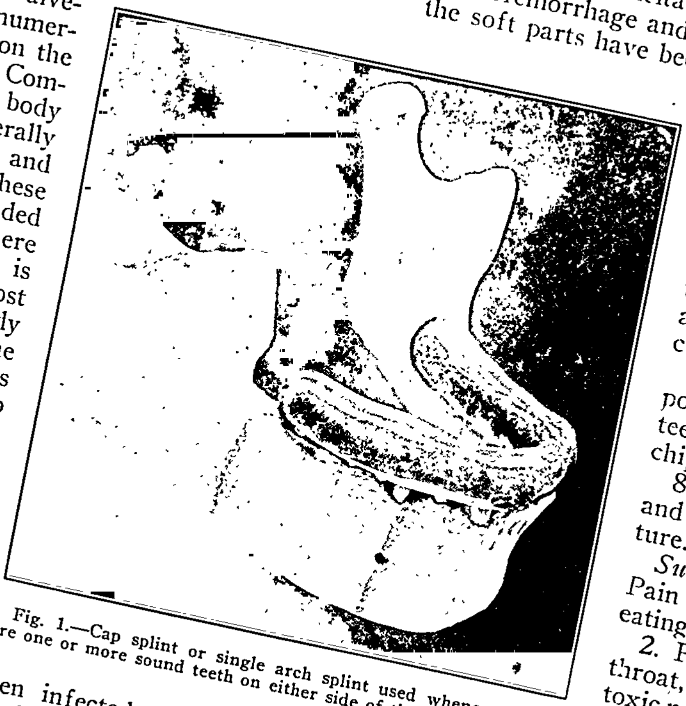

Fig. 1.—Cap splint or single arch splint used whenever there are one or more sound teeth on either side of the line of fracture.

Varieties of Fractures.—1. Complete. 2. Incomplete. 3. Single. 4. Multiple. 5. Simple. 6. Compound. 7. Comminuted or splintered. Any of the foregoing fractures may be complicated when nerves, blood vessels and other structures are involved.

Symptoms of Fractures.—1. Objective. 2. Subjective.

Objective Symptoms.—1. Deformity. Fractured portions of bone in faulty position, malocclusion of teeth; swelling and edema of soft parts, enlargement of glands.

2. Abnormal mobility of the fractured parts of bone or false point of motion.

3. Crepitus. The grating of the fractured end of one bone on another, obtained in complete fractures by holding one fragment of bone firmly between the fingers and moving the other on it.

4. Increased salivation, or drooling, very marked as a rule, and patient is forced to expectorate continually, owing to reflex excitations of vasomotor nerve.

5. Hemorrhage and ecchymosis, often present when the soft parts have been traumatized. The gums surrounding the point of fracture are often discolored and congested, owing to rupture of small capillaries, and extravasation of blood into the tissues.

6. Inability to close teeth together with much force on account of the lack of muscular control.

7. Teeth often loosened at point of fracture, and the teeth often fractured or chipped.

8. Infection and abscesses and necrosis at line of fracture.

Subjective Symptoms.—1. Pain in moving jaw when eating, swallowing, etc.

2. Pain and "soreness" of throat, due to absorption of toxic material by adenoid tissue of throat.

3. Inability to masticate.

TABLE 2.—NUMBER, KINDS AND LOCATIONS OF FRACTURES

	No.	Per Cent.
Number of Fractures:		
Single	951	89
Double	108	10
Triple	5	0.5
Quadruple	1	0.1
Kinds of Fracture:		
Simple	70	6.5
Compound	995	93.5
Location of Fracture:		
Median line	69	6.5
Right Side:		
Lateral region	112	10.5
Cuspid region	96	9
Bicuspid region	122	10.75
First molar region	86	8
Second molar region	123	10.75
Third molar region	66	6
Ramus	26	2.5
Condyle	3	0.6
Coronoid process	2	0.2
Left Side:		
Lateral region	65	6
Cuspid region	87	8
Bicuspid region	108	10.5
First molar region	94	9
Second molar region	144	13.5
Third molar region	70	6.5
Ramus	27	2.5
Condyle	2	0.2
Coronoid process	0	0

4. Pain on pressure at point of fracture.
5. Difficulty in talking and swallowing.
6. Partial and complete anesthesia around point of fracture, due to injury of branches of the third division of the fifth nerve and followed sometimes by slight anesthesia of the tongue.

Causes of Fractures.—1. Predisposing causes. 2. Direct causes.

Under predisposing causes we have:

A. Age. Both extremes of age—the very young child and in the old person. Young children's jaws do not fracture as easily as do those of old people, because the bone is more cartilaginous and springy, owing to the fact that the bones are not completely calcified. Around the ages of 6 to 10 years they are often greatly weakened by the eruption of the second teeth. Spaces are present in the body of the bone to hold these large erupting teeth, and quite often one finds the line of fracture through these cavities. In old persons, of course, all bones are more brittle, more poorly nourished, and the maxilla is often greatly thinned by the absorption that has taken place after the teeth have been lost. The most common age for fracture is between the ages of 30 and 40 years. Men during these ages are more often exposed to trauma, as their activities are greater.

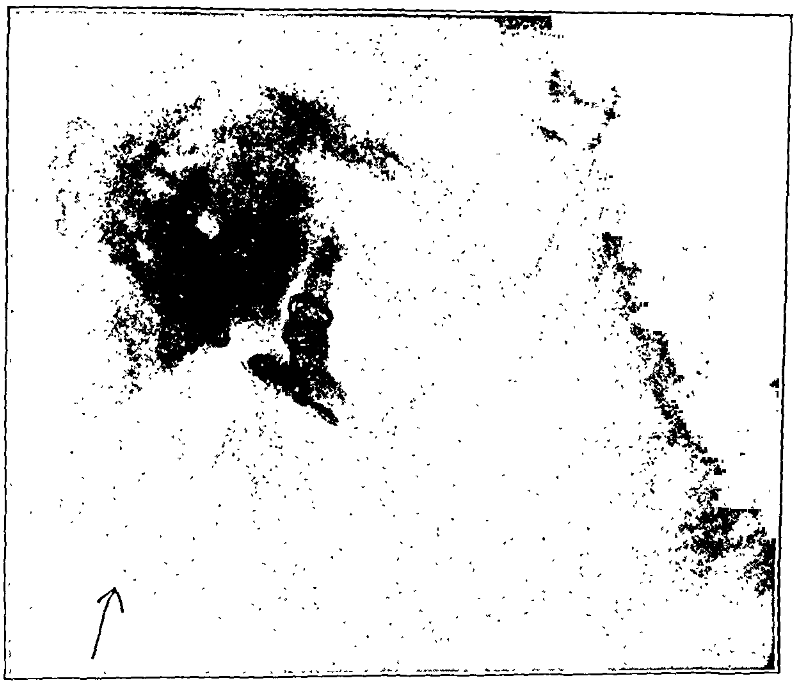

Fig. 2.—Impacted cuspid in line of fracture; a predisposing cause and an obstacle to healthy repair of bone.

B. Disease is another predisposing cause of fracture. Under this heading we have spontaneous or pathologic fracture:

(*a*) Necrosis of bone caused by infection, osteomyelitis, arsenic poisoning and phosphorus poisoning.

(*b*) Syphilis of bone.

(*c*) Tuberculosis of bone.

(*d*) Cysts of various kinds, including dentigerous cysts, in which large cavities are formed in the bone.

(*e*) Osteomalacia.

(*f*) Rickets.

(*g*) Tumors, odontoma, sarcoma, osteosarcoma, etc.

C. Occupation is a predisposing cause. Drivers, longshoremen, *chauffeurs*, waiters, pugilists, etc.

D. Sex: about ten times as common in man as in woman.

Under direct causes:

A. Blows of fist most frequent.
B. Blows of clubs, etc., next .
C. Automobile accidents.
D. Elevator accidents.
E. Railroad accidents.
F. Gunshot cases.
G. In extracting teeth. A complete fracture of the inferior maxilla is caused very rarely by the extraction of teeth, and I can only count one or two cases in which the jaw has been actually fractured by careless extraction.

Location of Fractures.—I do not agree with Stimson when he says that the most common seat of fracture of the lower jaw is at or near the median line (see tables).

Fractures at the *median line* show, as a rule, very little deformity as the parts are pulled on more evenly by the muscles on either side of the line of fracture. These fractures are not so common as in other regions of the jaw on account of the increased thickness at the symphysis.

The deformity at the *canine region* is not so marked as a rule, as the nearer to the median line the more even is the play of muscles, and the less deformity on this account.

The fracture at the *bicuspid region* often shows quite a marked deformity, the anterior fragment being drawn downward and backward, and the posterior fragment upward and outward.

Fractures between the first and second molar teeth may cause a good deal of deformity; generally the bone anterior to the fracture is depressed by the pull downward of the hyoid group of muscles. The posterior fragment is, as a rule, thrown upward by the contraction of the masseter and pterygoid muscles. The anterior fragment is also apt to be drawn backward, partly by the action of the hyoid muscles.

Fractures of the *ramus* itself do not show very much deformity, as the masseter and pterygoid muscles hold the fractured parts together as a rule. In these fractures the median line of the lower jaw does not coincide with the upper, as the whole lower jaw may be drawn over toward the fractured side if there is any overriding of the fractured parts of the bone. It is caused usually by a blow on the side of the face.

Fractures of the *condyle* are not so rare as the figures would show, but are not often diagnosed even with the aid of the Roentgen ray. A straight blow on the chin, forcing the jaw backward, generally causes this fracture, and quite often causes fracture of the base of the skull, by fracturing through the glenoid cavity, and also fracturing into the external auditory meatus. There is often a marked swelling around the point, and bleeding from the ear. Pain on moving the jaw, and the drawing of the entire jaw over toward side of fracture. These fractures are often very serious, one case being reported by Christopher Heath of London. At necropsy it was found that the glenoid cavity had been fractured and the patient had died from a large brain abscess.

Fracture of the *coronoid process* is extremely rare, as the coronoid process is so nicely protected by the zygomatic arch and its contents. The entire side of the face is often crushed without injuring this part of the inferior maxilla. Some authorities assert that the coronoid process is fractured by the sudden contraction of the temporal muscle, but this has not been proved conclusively.

Fractures posterior to the *third molar* at the junction of the ramus and the body of the bone are quite numerous, and the fractures in these cases are often in an oblique direction. Displacements in these cases are not very marked, as the parts are held together by the masseter and internal pterygoid muscles.

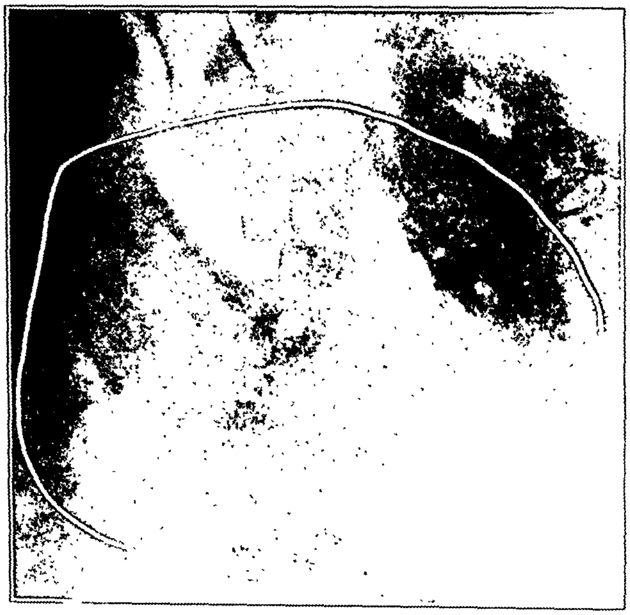

Fig. 3.—Fracture of tooth and jaw; tooth becomes infected and must be removed.

Single and Multiple Fractures.—Single fractures of the jaws are, of course, more common, but double fractures are frequently seen as shown by my tables. Triple fractures are quite rare and I have seen only four or five in the foregoing series. Quadruple fractures are extremely rare, and I have seen only one case. Teeth are often loosened and fractured in complete fractures of the bone. Multiple fractures are generally more painful, owing to the fact that there is usually more trauma, and the fractured ends of bone impinge in more than one place on the inferior dental nerve. In these cases, when trauma has been great there is often an area of anesthesia around or near the line of fracture. This condition often remains long after the jaw has united.

The location and number of fractures of the lower jaw depend a great deal on the articulation of the jaws, and to the arrangement of the occluding teeth. Also to the manner in which the trauma is produced. Slight dislocation of the bone often occurs when the bone has been fractured in more than one place, especially when the fractures are bilateral, as the shape of the bone is not supported and its arch collapses. By the play of the powerful hyoid muscles, the bone is then drawn downward and the condyles are often displaced slightly from the glenoid cavities.

TREATMENT

In treating fractures of the jaws the general hygienic condition of the mouth must be carefully considered and the general physical condition of the patient noted. The teeth should be cleansed first of all—not too minutely removing all calcareous deposits, but the soft food particles and infectious material should be removed from the teeth and soft parts. The gums and teeth should be cleaned every two hours by means of cotton swabs on a stick soaked in hydrogendioxid and water (equal parts). A roentgenogram should now be taken. The next step should be the extraction of any broken-down decayed roots, and any loose teeth near the point of fracture. If these are not removed they often cause abscesses which are generally very troublesome. After the mouth is rendered as clean as possible, lacerations of gums and soft parts have been treated, and roots have been removed, the next important step is to consider the means of proper coaptation and fixation of the bony parts.

If there is very much edema and swelling of the soft tissues, it is sometimes well to apply hot or cold compresses, and wait until the swelling subsides, meanwhile keeping the mouth clean, and the jaws held together with a Barton bandage.

In taking up the matter of fixation of the bony parts, we must consider the mechanics of the case. We must think of what forces are going to act on the different parts of the bone, and how much strength it will require to hold the fractured parts together for a given time.

It is comparatively easy to immobilize a fractured leg or arm, but a different story to keep the inferior maxilla from moving. The inferior maxillary bone is moving continually. The powerful muscles of the jaws are pulling and contracting in different directions all the time. The fractured parts move every time the patient eats, swallows, coughs, talks, sneezes, etc., unless held by a well-constructed mechanical appliance. We must remember that the average splint will remain in the mouth about thirty days under more or less constant strain. These appliances should be strong, comfortable and as small as possible, and should be arranged so that the patient can chew with splint in position if possible. Of course the articulation of the teeth should be carefully studied and the functions of jaw and teeth accurately restored as a final result.

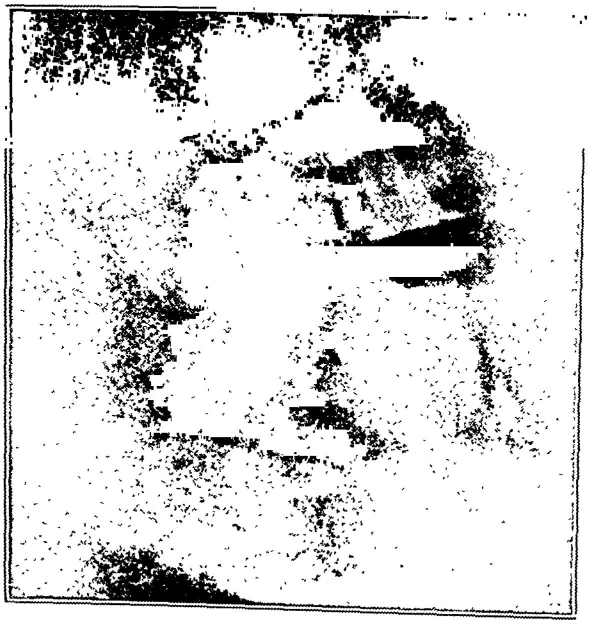

Fig. 4.—Gunshot fracture; cap splint in position.

In discussing the actual method of splinting fractured jaws it will be well to consider again the location of fractures.

In fractures of the *median line,* when there is not much deformity, and when there are one or more sound teeth on either side of fracture, the best method to adopt is the use of a cap splint or single arch splint made of rubber or metal. Wires or interdental splints should never be used in these cases, as they are clumsy and dirty, and the patient is unable to chew with them.

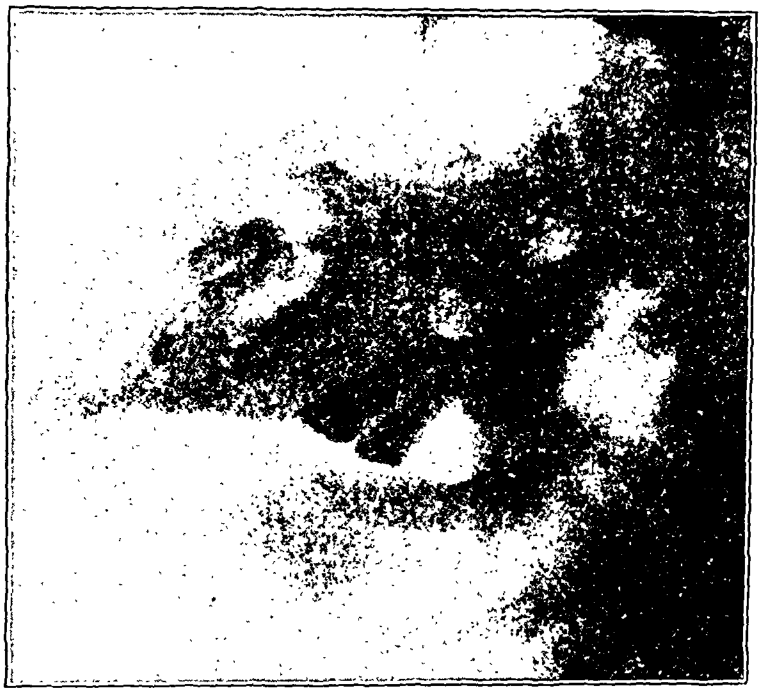

Fig. 5.—Pathologic fracture; no history of any trauma, but long history of chronic abscesses of jaw. Fracture occurred while patient was eating crust of bread.

In fractures at the *molar region,* when there are one or more good teeth, the cap splint can be used, but if the teeth are not strong, wiring the entire lower jaw to the upper is a good procedure for about ten days, until there is partial union, and then the cap splint may be put on. When there is much deformity in this case, wiring the upper and lower jaw together, after applying Angle's bands, is a good plan. Mouths become very foul, and septic poisoning of the entire system may follow and also infection of the respiratory organs when the jaws are wired together for a long period. Carl Beck reports a case of inspiration pneumonia which ended fatally because of the filthy condition of a mouth resulting from the fracture of the inferior maxilla.

Fractures *back of the third molar,* and in the ramus are best treated by interdental splints, and wiring jaws with Angle's wires. The wiring method is the best if there is much deformity, as sometimes it is difficult to force a jaw into an interdental splint and hold it there with a bandage, especially if the deformity is marked.

I disagree with Frederick J. Cotton when he advises the open operation and surgical wiring of fractures in this region. It is in most cases unnecessary. It is of course impossible to hold the ramus by any splint in the mouth, but the anterior fractured end of bone can be held to the ramus by wiring the upper and lower jaws together. In children all fractures are best treated by small modified interdental splints. The teeth are not strong enough to wire and it is difficult and unsatisfactory to cement a cap splint on the teeth.

Surgically wiring through the body of the bone for fractures in any location should not be done. Very poor results are obtained by this method, as most cases terminate in infection and necrosis. We have not had to resort to this treatment in over 1,200 cases.

A method lately used has been the screwing of a Lane plate to the under border of the jaw and good results have been obtained, but this method is unnecessary. Outside splints or apparatus on the face are seldom needed and have not been used at all by us in over 1,000 cases treated at the college.

COMPLICATIONS

Infection is the chief source of annoyance and danger in fracture cases. A large percentage of all compound fractures are infected, and in many of these cases there is necrosis later. Abscesses often form at the point of fracture, and later sinuses form which are apt to break on the face owing to the fact that the pus gravitates downward. Comminuted or splintered fractures are nearly always followed by abscesses and necrosis. Union in these infected cases is generally delayed, and suppurating sinuses may continue for months. A good deal of necrotic bone in these cases is eventually thrown off.

Deep abscesses of the neck are often dangerous, and may extend along the deep fascia into the anterior mediastinum. Edema of the glottis may follow and fatal results occur. Ludwig's angina sometimes results.

Faulty union is quite often encountered, often in children when the bones sometimes unite before one can get on a suitable appliance.

Partial and complete ankylosis often occurs in fracture of the condyles, resulting in loss of function and malocclusion.

Non-union or pseudarthrosis occurs infrequently, generally owing to loss of bone following comminution after infection and necrosis, and perhaps aided by some constitutional disease such as syphilis, tuberculosis, etc.

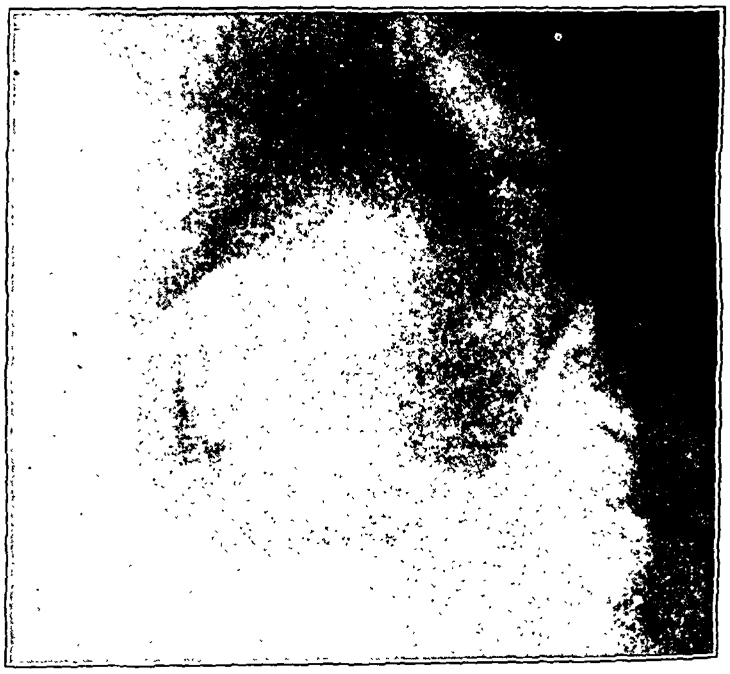

Fig. 6.—Double fracture which was badly infected; shows marked loss of bone because of exfoliation; poor result obtained.

We have had two cases of failure to unite in the foregoing series of 1,065 cases. This condition is also due to fibrous tissue and torn ends of periosteum coming between the edges of the bone and not allowing them to unite. Dr. Walter C. Cramp[1] in 1911 reported a case of rupture of the facial artery due to the fracture of the inferior maxilla. This is a very rare occurrence and I believe the only one on record.

---

[1] Cramp, Walter C.: Fracture of Inferior Maxilla Complicated by Complete Division of Facial Artery, Med. Rec., New York, Sept. 2, 1911.

Salivary fistula may sometimes result as a sequence to fracture of the lower jaw, but this condition is extremely uncommon and does not occur unless the soft parts are greatly traumatized.

The diet of patients being treated for fractured jaws and wearing splints is one of a good deal of study and experimentation. It varies a great deal with the individual. My general method is to give the patient as many raw eggs (from four to six) per day and as much milk as possible (from 1 to 2 quarts) and feed every two hours. The diet ought to be carefully worked out for each patient, and the bowels, of course, must be kept open daily by means of efficient laxatives. Patients that have been wired by the Angle method for a month will often lose from 15 to 20 pounds. This, of course, is very weakening and one reason why the Angle wires and bands should not be used if other methods will suffice.

CONCLUSIONS

The inferior maxillary bone on account of its position and shape is the most frequently fractured bone of the face and about tenth on the list of all bones of the body to be fractured. About 98 per cent. of all fractures of the body of the bone are compounded when there are teeth present. And thus it is the most frequent bone to suffer a compound fracture. The fracture of this bone becomes infected on account of the fractures being compound, more than any other bone. The patient suffers great pain from injury to the inferior dental nerve and also from the inability to swallow, eat, drink and cough.

The fracture is about ten times as common in man as in woman. The most common age for the fracture of the bone is between 30 and 40. The most frequent cause of the fracture is a blow of the naked fist. A line of fracture is most often at the region of the bicuspids on the left side. Fractures of the lower jaw depend a great deal on the occlusion of the upper and lower teeth. Fractures of the condyles are rare but are often followed by bony ankylosis. Fractures of the coronoid process are extremely rare and occur only when the zygomatic arch and the side of the face are severely crushed. Great care should be exercised in keeping the mouth clean in the treatment of fractures of the jaw. A cap splint or single arch splint should be used whenever there are one or more strong teeth on either side of the line of fracture to which the splint may be cemented. The interdental splint or intermaxillary splint should be used only in children, in edentulous mouths and in fractures posterior to the third molar when the upper and lower jaws cannot be wired together by means of Angle's wires and bands.

The open operation or surgical wiring of the fractured ends of the bone is unnecesary and generally results in infection and necrosis. The inferior maxillary bone can be more accurately reduced and held in better coaptation than other bones, as direct force can be applied to it by means of appliances attached to the teeth. Non-union very rarely occurs and is generally due to faulty or delayed treatment.

A roentgenogram should always be taken to ascertain the line of fracture, to discover the presence of impacted teeth and to note any infections or abscess conditions at the apicies of the teeth near the point of fracture.

ABSTRACT OF DISCUSSION

Dr. G. V. I. Brown, Milwaukee, Wis.: I wish Dr. Dunning would elaborate a little on a few matters which are sometimes disturbing to people who see fractures only once in a while. That is, the way he meets the conditions of the patient at the time of arrival at the hospital, or at least when called in an emergency. Dr. Dunning spoke casually of the treatment of these cases, but some, I think, require a little more treatment than he described. I find it necessary sometimes to make a temporary splint to give comfort, and I have made it quickly and rapidly out of a modeling compound. It is easily held in position by the use of the Barton bandage and will make the patient comfortable for a sufficient period of time, if necessary, to make it possible to do other work. When a man is thrown from an automobile he usually receives some other injury besides fractures and most of the time those are the things that give us most trouble. So that it is necessary sometimes to take care of cases through a critical period before we can adjust the fractures. I know that in his experience with 1,065 cases Dr. Dunning's observations would be valuable. I would ask him to speak about the manner of adjustment in these cases. I agree with him that, most of the time, a fracture of the condyle will adjust itself, if the rest of the jaw is held, with much less trouble than we can adjust it by wiring. There are conditions, however, due sometimes to the shape of the fracture and degree of the angle of the fracture, that should modify this statement. Because one case adjusts itself nicely without being held and without wiring, it would not necessarily follow that other cases, in almost the same situation perhaps, would do the same, because the angle of the fracture has to do with that. I think we agree that too much is done in fractures of the jaw. The less we do for them after using an appliance which will permit of constant surveillance, as far as possible, and give mobilization, the better. Unfortunately, too much is done in the way of cutting in and wiring the jaw. I do not believe in temporizing at all in the case of a jaw that requires wiring, but I agree with Dr. Dunning that many are wired which should not be. Then again comes in as a part of this question, the manner of adjusting the wires, etc. We should understand the advantage of all methods which have been found most frequently successful.

Dr. M. I. Schamberg, New York: Dr. Dunning's statistics are intensely interesting, and I am sure that his experience in these cases, when we read them over carefully in his paper, should help us materially, particularly those of us who see far fewer cases. I have seen a large variety, but in no sense a large number. I have found, as has Dr. Dunning, the Roentgen ray intensely valuable, and in fact almost essential to absolute accuracy in most of these cases, for the reason that so frequently one will see fractures with spiculae of necrosed bone, or infection, or at times portions of the root, and in one instance both spiculae of bone and a piece of the root protruding into the fractured region, which would retard the healing. Another case to which I refer was a pathologic fracture of marked extent in which the Roentgen ray showed what looked like a compound comminuted fracture of a jaw that was ordinarily thick. I was inclined to suspect that this was produced primarily by arsenic necrosis, and this necrosed bone in the jaw was separated in many places. We dealt with this case in a manner that would not appear to you to be surgically correct, but by which the case culminated satisfactorily. All that appeared to be bone was nothing but a thin matrix and this acted as a matrix for new bone to form. The jaw was splinted on each side, and this patient wore the splint at an old age, resulting in the reduction of the fracture and the formation of a very useful jaw. The splint was removed after the patient wore it for six months and the result on that side is wonderful. I have a similar case in which there was extensive necrosis of the jaw and in which, after a similar appliance was worn, complete regeneration of the bone took place. I believe that much can be done by the application of what may be termed surgical prosthesis without real surgery, to bring about results that heretofore have not been achieved.

Dr. Theodore Blum, New York: This appliance which Dr. Schamberg has spoken of is really not a splint in the ordinary sense of the word, but is the splinting of the jaws by means of a sliding joint. One point with regard to fractures is the splinting of the lower jaw to maintain its mobility, and the same principle is carried out in these pathologic fractures in a different way. At the University of Pennsylvania we were taught by Dr. White that there were three points to be remembered in the treatment of fractures. First, reduce the fracture; secondly, maintain mobilization of the joint on either side of the fracture, and thirdly, maintain nutrition.

Dr. W. Wayne Babcock, Philadelphia: Anyone who has gone to the trouble that Dr. Dunning has in collecting the data on such a large series of cases as this, nearly eleven hundred, every one of a single bone, is deserving of great credit, because it clarifies our knowledge with regard to certain points which have been in dispute, and confirms things which may have previously needed confirming. We are practically agreed as to the plan of treatment; as to the advantage of getting away from some of the older appliances, especially the interdental splint, and relying on operative intervention. Nature has already done about the worst she could do in the accident, and then it has been the tendency for the surgeon to step in and further traumatize the parts, and it is not surprising that necrosis and various ill results have followed. Then again, in these cases sometimes the question arises as to the external wound. In most cases we are safe in cleansing and closing any external wound on the face. If the fracture is compound, let it be compound in the mouth and not from the face; and if one has been careful, as a rule, I believe the face would heal and drainage will take place in the mouth and to the same degree. Then as regards teeth that are somewhat loosened adjacent to the fracture, as a rule, I believe, Dr. Dunning feels that these may be left at the time to see what the results will be. Frequently teeth which look as though they must be sacrificed, if followed up, gradually become fixed; and of course, later on, spiculae of bone or any tooth that has become loosened may be removed at a time when the deformity may not be so great, or at a time when the removal may not bring about a greater deformity.

Dr. Henry S. Dunning, New York: I agree with Dr. Brown that a great many of these patients need attention other than that pertaining to the jaws. For instance, in one case, a woman was hit by a taxicab and among her injuries was the fracture of the jaw. This patient was unconscious when picked up and was suffering from a fractured rib and arm and concussion of the brain. This brings out a point in the paper that many fractures of the condyle are accompanied by fracture at the base of the skull, or fracture of the posterior wall of the glenoid cavity. I think Dr. Beck reports a case in which the patient died from abscess of the brain, due to a blow on the chin causing fracture of the base of the skull. I treat a great many of these cases in the hospital when the patient has received other injuries and has sometimes brain symptoms. I think the reason why the "knock-out blow" on the point of the chin is so famous is because the shock is so severe in a region that is close to the brain. The condyles are forced into the glenoid fossa, and being wedge-shaped, often cause a fracture into the cranium. With regard to surgical wiring, I have seen only one or two cases in over twelve hundred in which wiring had to be resorted to. Will Dr. Schamberg, who has had so much experience in the use of the Roentgen ray, say what angle is best from which to obtain a good roentgenogram of the condyle? In one case nineteen roentgenograms were taken of the fracture, and the one shown was the best we could get and the patient was put in every conceivable position to get that. In most of the other roentgenograms we had the vertebrae overlapping the condyle.

How does Dr. Blum keep the two ends of the bone in apposition and allow the patient movement of the jaw at the same time, in fractures posterior to the third molar? I believe that it is poor treatment to wire the upper and lower jaws together when any other appliance can be used that will permit the patient to use the jaw while being treated. I never do it unless the fracture is posterior to the third molar, or for some reason the teeth in the mouth cannot hold a splint to advantage. It is difficult often to keep the mouth clean when wired. Dr. Beck reports a case of inspiration pneumonia from a filthy mouth, wired for some weeks after a fracture, in which the mouth could not be kept clean, and in this case the patient died. I agree with Dr. Babcock that if we can possibly close the external wound, we should do so. Of course these wounds are mostly dirty or infected wounds and must often be drained. I think it is best to close these wounds partially, as soon as possible, but to leave one end open for a few days and allow it to drain and then later to fill in with granulations.

A PORTABLE POSITIVE-PRESSURE APPARATUS FOR ADMINISTRATION OF ETHER BY INTRATRACHEAL INSUFFLATION

ALLIE W. WILLIAMS, M.D.
Major Medical Corps, U. S. Army
WASHINGTON, D. C.

On account of the advances in head, neck and chest surgery, made possible by the use of the Meltzer-Auer method of administration of ether by intratracheal insufflation, I decided, at the suggestion of Dr. William M. Sweet of the Department of Experimental Surgery, University of Pennsylvania, to construct an apparatus suited to the needs of service conditions. In order to meet these conditions, it was necessary that the apparatus should "work" at all times, should be made easily transportable, and non-destructible by age from storage or climatic conditions. As a few parts of this apparatus had to be made of glass, as far as possible standard articles only were used.

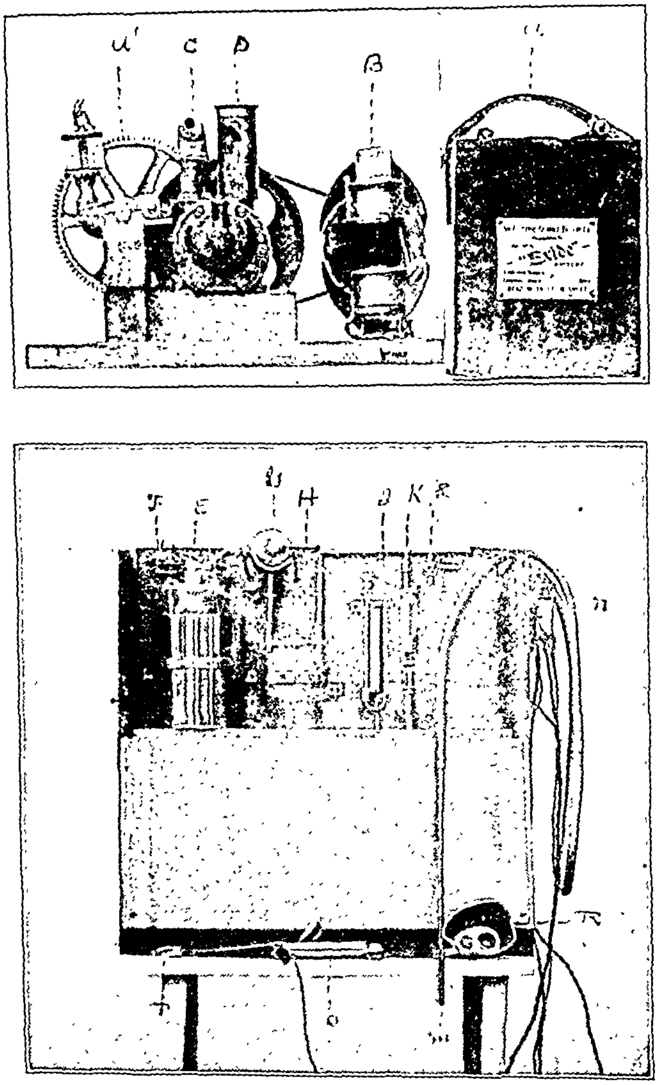
Through the courtesy of Dr. Sweet, Dr. Charles H. Frazier and Dr. George Müller of the University of Pennsylvania, this apparatus was tested on both animals and patients at the University Hospital, and was exhibited in 1912, at the annual meeting of the American Medical Association, at Atlantic City, and the Military Surgeons' Association at Baltimore.

Recently I have had the opportunity of giving it a thorough test under field-service conditions in the surgical work at Field Hospital 3, Texas City, Texas, and since May 30, 1914, at Vera Cruz, Mexico. During this time the apparatus was essential to the successful performance of four surgical operations: (1) A plastic operation on the chest-wall for tuberculous necrosis of ribs, with tuberculosis of pleura and lungs; (2) dissection of bronchial fistula of neck; (3) resection of frontal bone for frontal sinusitis; (4) tuberculous abscess of neck. In the two latter operations the anesthetic was administered with this apparatus, using pharyngeal instead of intratracheal insufflation. The anesthetic was administered by Capt. H. C. Michie, Jr., Medical Corps, U. S. Army. That Captain Michie refers to it as "the lazy man's way of giving an anesthetic" is an evidence of the ease with which he was able to administer it with this apparatus.

At Philadelphia, while testing this machine, a curious incident happened at the University Hospital. A physician with some experience in the use of the Meltzer-Auer method of producing positive pressure in the lungs by intratracheal insufflation anesthesia, expressed some doubt as to the mechanism of distending the lungs against the chest-wall by means of introducing air under pressure through a catheter which was only half the diameter of a man's trachea, asserting that an increase in incoming air would cause a corresponding increase in outgoing air between the catheter and the trachea, to the extent of preventing increased intrapulmonary pressure. To convince him and clear the question beyond possibility of any doubt, an animal was anesthetized by this method and both sides of the chest-wall were opened freely; with this apparatus, by increasing the pressure to 20 mm. as registered on the manometer, both lungs came well up and filled both openings. By further increasing the intrapulmonary pressure I was able to distend the lungs well out of the chest cavity.

With this apparatus operations can be done on the chest-wall without the hazard of a fatality from pneumothorax. The lungs may be operated on, provided hemorrhage is controlled by ligature or cautery, under practically the same degree of risk as in operating on the abdominal viscera. As remarked by Keen, "greater advances have been made in lung surgery in the last ten or twelve years, through the agency of the Meltzer-Auer method of maintaining positive-pressure and negative-pressure cabinets, than in all previous years in the history of surgery." The Meltzer-Auer method of maintaining positive pressure in the lungs has very largely superseded the use of negative-pressure cabinets on account of being simpler in its use, more satisfactory in its results, and far less expensive in cost of apparatus.

While stationed in Philadelphia in 1912, I had the opportunity of observing in Dr. Charles H. Frazier's clinic, at the University Hospital, the administration of this form of anesthesia in some forty odd cases, the apparatus used in Dr. Frazier's clinic being one devised by Dr. George P. Müller, Dr. Frazier's assistant. On one occasion when I gave the anesthetic for Dr. Frazier the patient was a man 55 years old who had a partial excision of the tongue done for carcinoma, with extensive dissection of the glands of the neck. He had been a heavy drinker, and his arteries were markedly sclerosed. At the end of an hour's anesthesia, Dr. Frazier remarked that his pulse was as good as it was at the commencement of the anesthetic.



Portable positive-pressure apparatus for ether administration; motor, blower and hand mechanism which fit in lower compartment, are one-third larger for illustrative purposes than apparatus in case. The entire apparatus contained in a box, weighs about fifty pounds and is the size of a suit-case.

Reference has been made by a few persons to the greater liability of ether-pneumonia from intratracheal insufflation. This has not been proved in over a thousand collected cases. I am inclined to believe that ether-pneumonia would be less by this method for the following reasons: 1. The catheter is sterile and is passed through a sterile Jackson bronchoscope introducer, no foreign material being introduced with catheter. 2. The return current of air bars the introduction of foreign matter after the anesthetic is commenced. 3. No chilling of tracheal or bronchial mucosa results from introduction of the etherized air, as after passing through the 3 feet of rubber tubing connecting the apparatus with the catheter, the air introduced has returned to room temperature.

It has been observed at Peck's clinic at Roosevelt Hospital, and my observations at Frazier's clinic at the University Hospital, Philadelphia, were, that nausea and vomiting were far less common after intratracheal insufflation anesthesia than after administration of ether in the usual way with a mask. This is accounted for by the fact that on discontinuing the anesthesia by intratracheal insufflation, it is the custom to blow out the lungs with fresh air, thus preventing the patient from swallowing ether-laden mucus when coming out from the anesthetic.

This apparatus while primarily designed for maintaining positive pressure in the lungs in conjunction with anesthesia, is of almost equal value in head, neck and spinal surgery, in that it removes the anesthetist from the field of operation, and can be administered with facility in any position of head and body.

Also, in the hands of a medical man, its service is equal to that of a pulmotor, air or oxygen being substituted for the etherized air. A valve or blow-off readily controlled by the operator admits of artificially distending and collapsing the lungs eighteen to twenty times to the minute. It has the advantage over the Sylvester and other forms of manual artificial respiration in that the machine does the work without wearying the operator. Thoroughness in the application of artificial respiration would not be sacrificed because the operator was exhausted.

The claims made for this apparatus is that it will work at all times. For convenience it is usually operated by an Exide storage battery; if for any reason the storage battery fails, by a readily adjusted gearing it is easily operated by hand mechanism. This hand mechanism is operated by grasping the handle located to the front and on the outside of the case in which the apparatus is contained, and by a slow and comparatively noiseless turning of crank connecting the gearing, the requisite pressure is obtained with little or no effort.

This I consider one of the most valuable improvements on this apparatus over that of other apparatus as suited to the needs of service conditions. The hand mechanism being substantially made of cast iron, no deterioration would result with storage or continued use in tropical climates. This cannot be said of the foot-bellows, which is made of leather and prior to this has been used as the substitute power for this kind of an apparatus. The apparatus is made by the Pierce Instrument Company, Philadelphia, and is described as follows:

"Power is derived from an Exide storage battery, *A*, is transmitted to *B*, an Edison motor (or power may be derived from hand mechanism *A'*. Air enters *C*, a positive pressure (hypress) blower, passes through *D*, an oil separator, by tubing to *E*, a standard three-necked Woulfe bottle, where air is filtered and moistened by gauze. This bottle sits in a copper tank and can be heated by hot water (this has, however, not been found necessary). A stop-cock is located at *F*, to allow escape of air not required for pressure.

"The air after being filtered passes out of distal neck of Woulfe bottle through a simple valve, *G*, where as much of the air current as is desired is made to pass over the ether in container, *H*. The amount of air passing over ether is indicated on index just over valve, *G*, which is easily regulated by hand. A mercurial manometer, *I*, indicates pressure of etherized air in lungs, and a mercurial blow-off, *K*, prevents excessive intrapulmonary pressure. To allow the lungs to partially deflate, the stop-cock, *L*, is opened and closed four or five times a minute. The etherized air passes out through 3 or 4 feet of rubber tubing to the tracheal tube, *M*.

"The Jackson laryngoscope, *O*, containing a small incandescent light is lighted by storage battery regulated by rheostat, *N*; *P* is a specially designed clamp for holding tracheal tube in position; *R* is an ether mask for use in etherizing patient before introducing the tracheal tube.

"The tracheal tube is introduced after the patient has been thoroughly anesthetized by the mask method. A No. 24 F. tracheal tube is the size of the catheter used. The tube is passed down the trachea a distance of from 26 to 30 cm. until the end of the tube comes into contact with bronchial tubes and their bifurcation, it is then withdrawn 1 or 2 cm., and the anesthesia by intratracheal insufflation is commenced."

The safety of this method of anesthesia is attested to by Dr. Samuel Robinson in a paper before the Massachusetts Medical Society, in which he makes an analysis of fourteen hundred cases of anesthesia by intratracheal insufflation with the statement that "intratracheal insufflation anesthesia is as safe a method of ether anesthesia as we have at our disposal regardless of the seat of operation."

Legal Record of Births.—The registration of a child's birth forms a legal record that is frequently useful and may be of the greatest importance. It establishes the date of birth and the child's parentage and legitimacy. It may be required to establish the child's age for attendance at public schools, for permission to work in states where children below a certain age are not allowed by law to be employed; to show whether a girl has reached the age of consent, whether individuals have attained the age when they may marry without the parent's permission; to establish age in connection with the granting of pensions, military and jury duty and voting. It may be necessary in connection with the bequeathing and inheritance of property or to furnish acceptable evidence of genealogy, and, in fact, may be important and useful in possible events too numerous to mention.—John W. Trask, Supplement No. 12, Public Health Reports, April 3, 1914.

RESECTION OF THE KNEE-JOINT FOR TUBERCULOSIS *

M. S. HENDERSON, M.B. (Tor.)
ROCHESTER, MINN.

Resection of the knee-joint is an old operation dating back to Filkin[1] of Northwick, who performed a successful resection in 1762. He was followed by Park[2] of Liverpool, in 1782; by Moreau[2] in France, in 1792, and Mulder[2] in Holland, in 1809. Buck's[3] operation in 1844 is given credit of being the first in America. In pre-Listerian days the operation was not in favor on account of the frightfully high operative mortality. The statistics of Heineke[4] (1866) reporting eleven cases with four successes and seven deaths emphasize this fact. Ollier's[5] statistics up to 1870 show a corresponding mortality, he having performed seventeen operations with but one recovery. After the introduction of antisepsis, Ollier's mortality dropped to 10 per cent. To-day, in properly selected cases, the operative mortality may be considered practically nil.

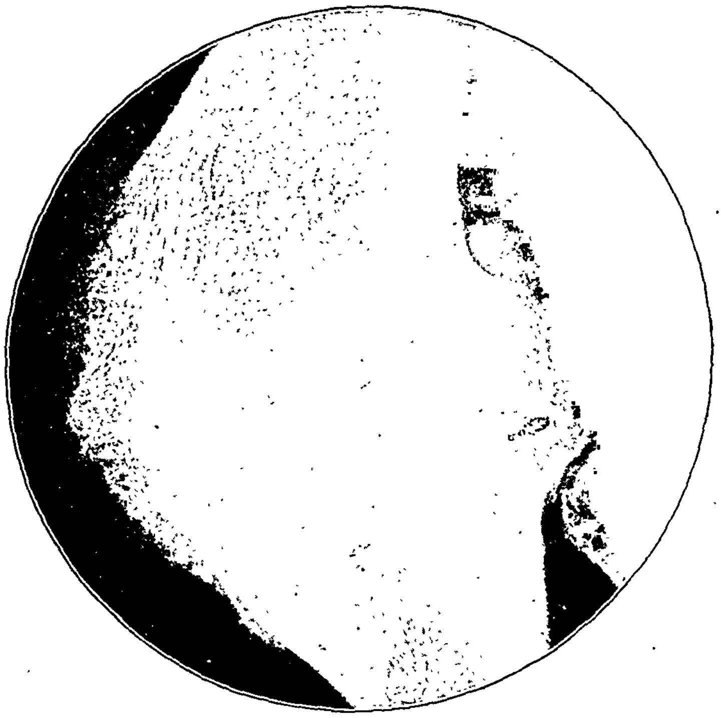


Fig. 1.—Bony ankylosis; result of acute infection. Note the tendency of the medullary cavity of the femur to become continuous with the medullary cavity of the tibia.

As a functionating knee rarely follows the treatment of tuberculosis of the knee in an adult, ankylosis with cessation of symptoms often is the best result to be hoped for. In an adult, however, tuberculosis *per se* rarely brings about an ankylosis. It may more readily occur after the formation of abscesses and discharging sinuses following secondary infection.

The history of cases in our clinic presenting a bony ankylosis of the joint (Fig. 1) is very different from those cases of the tuberculous type to be considered in this paper. The onset is sudden, coming on frequently as a result of exposure to the cold. Gonorrhea may be a cause. Tonsillitis or sore throat is often a premonitory symptom; chills and fever ensue, and the joint or joints become involved, causing swelling and pain so excruciating that opiates only partially control it. The patient is usually allowed to assume any posture that gives him greatest comfort. Symptoms usually subside in from six to twelve weeks. Ankylosis is apt to occur in the position in which the joint was held during the acute stage of the disease. The soreness gradually passes away, the general health returns to normal, but the patient is crippled by the mechanical inconvenience of the limb involved. This is the type of case which promises the best results in arthroplastic work.

The type of tuberculous cases under discussion gives no such history and presents no bony ankylosis (Fig. 2). The onset is slight and trauma may or may not be a definite factor. Accurate statistics are difficult to obtain on this point. The history records remissions, but never entire freedom from some inconvenience. After years of gradually increasing difficulties, many patients request amputation. We have yet to see any joints of this type attain bony ankylosis by treatment under casts and braces, unless secondary infection has been a complication.

Undoubtedly, in some cases, tuberculosis of the knee-joint is cured by conservative treatment in the early stages. Definite information would be collected if aspiration were done in early cases and the guinea-pig test made. This test has proved to be a great aid in cystoscopic work and should be of the same value in the diagnosis of obscure lesions of the joints.

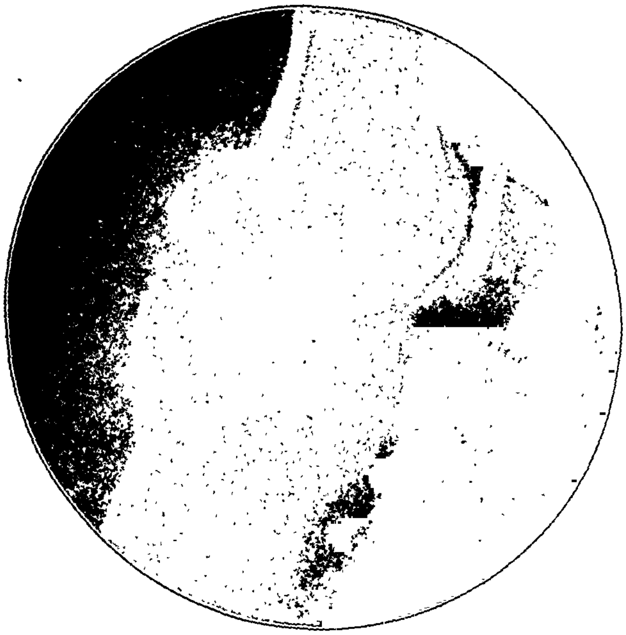

Fig. 2.—Tuberculosis of the knee of six years' duration in an adult. Destruction and disintegration of all constituents of the joint. No evidence of bony ankylosis.

The question arises, What shall be done with these cases? Conservative measures should be tried for a reasonable length of time, though in our experience with cases of tuberculosis of the knee-joint in adults resection is usually the final solution.

The selection of cases, or rather, their preparation for operation is important. The results are almost always good if the patient is operated on in the quiescent stage. Pain is much less and swelling and edema of tissues followed by sinuses is no postoperative complication if this r Extension and rest in bed are proba of quieting the condition.

Generally speaking, since the results are less fa- able in patients past 50 than in those between 20 and 40, it is even more important that the former be operated on during the quiescent condition. A disastrous result leading to amputation is very likely to prejudice the surgeon against a procedure which, if done under the proper conditions, gives excellent results.

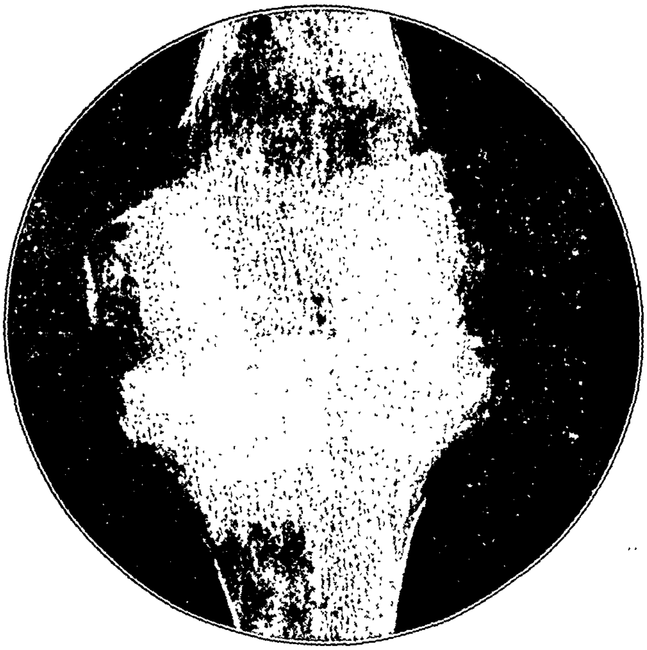

Fig. 3.—Radiograph of specimen. Ankylosed knee-joint three years after resection. Amputation because of pain and formation of abscesses.

This paper is based on a series of thirty-seven patients who were operated on before March, 1913, and whose histories have been subsequently traced. The records of the Mayo Clinic show sixty-six resections of the knee-joint before that date, but only thirty-seven could be traced. Up to May, 1914, seventy-eight resections had been done for tuberculosis of the knee with no operative mortality. Only cases have been selected which, by a review of the history, operative findings and pathologic report, were undoubtedly tuberculous. In some, the diagnosis before operation had been cleared up by the guinea-pig test. An attempt has been made to classify the symptoms, but such detailed report would be out of place here. The average age of patients in the sixty-six cases was 27 years; forty-three of these were males, twenty-three females. The average duration of symptoms before operation was eight years. These patients all came for consultation on account of varying degrees of pain, disability and deformity. Thirty-seven patients were traced, and of these thirty-two may be classed as cured since the functional results were good; two returned for amputation and three died. Of the three who died, full information could not be obtained. In one the cause of death (four and one-half years after operation) was given as tuberculosis, but without stating the site of the lesion. Two died of tuberculosis of the lungs; one, one and one-half years, and the other, three years after operation. Very encouraging and grateful letters were received from the patients who were cured, many of whom had gained from 40 to 60 pounds. Practically all were able to resume their full duties. Two stated that there was still some motion in the knee which caused inconvenience and feeling of insecurity, but that they were free from pain. Rather than resect again, two pieces of bone will be grafted to induce ankylosis and relieve these patients. Two patients of the thirty-seven have persisting sinuses. In one case the sinuses persisted even though there was firm bony ankylosis. This patient also had pulmonary tuberculosis. The abscesses which formed in the region of the knee, causing pain and loss of sleep, were opened and drained as they appeared. Vaccines, tuberculin, etc., were used to no avail. Three years after the resection, amputation was performed and the patient now gets about on an artificial limb; tubercle bacilli have disappeared from his sputum and the roentgenogram of the lungs shows marked fibrosis. A dissection of the removed joint shows firm bony ankylosis (Fig. 3). Each sinus led down to a superficial bony erosion, resembling the so-called tuberculous periostitis. Such sinuses may occur in patients operated on in an acute stage of the condition.

The time spent by the patient in absolute rest prior to operation is well repaid by the easy and shortened postoperative convalescence. In the acute stages with threatened rupture of abscesses, it is better to insist on rest and aspiration of the abscess, which, in a certain percentage of cases, will avert further formation of abscesses and sinuses. Three patients with sinuses were operated on: One of these, operated on in the acute stage in our clinic, had an amputation elsewhere three months later and died of cause unknown. In the two other patients operated on the sinuses healed within four months.

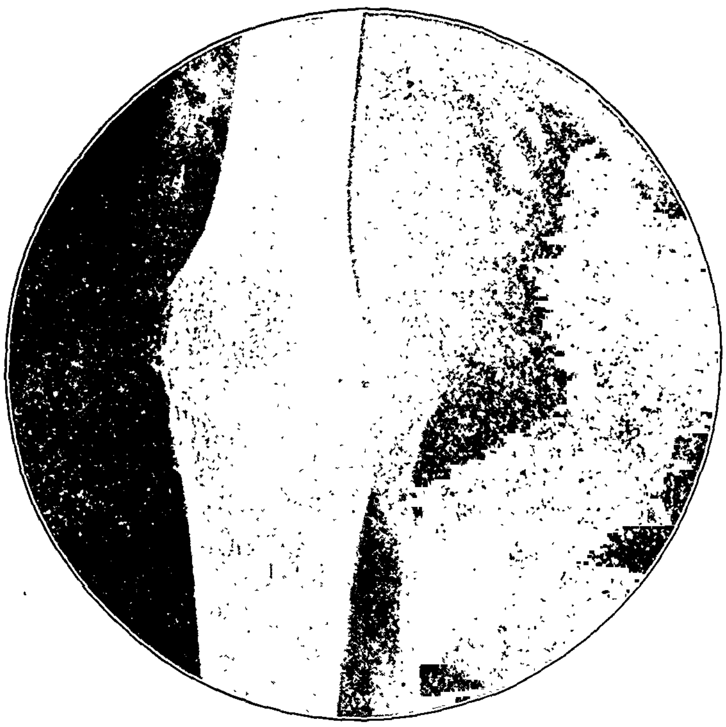

Fig. 4.—Bony ankylosis one year after resection.

The social status of the patient influences to a great extent the treatment. Obviously, a person of sedentary occupation can more readily put up with inconvenience of a brace or case than one engaged in active pursuits. The latter will be better off with a stiff knee which allows him to get about without pain than with braces and crutches.

The specimens were examined from a pathologic point of view to see if any definite data could be collected as to whether the primary focus was in the bone or the synovial membrane. This was impossible to determine owing to the advanced stage of the disease and the amount of bone destruction. All evidence of the early condition was destroyed, the picture showing only the terminal stage. Ely[6] has stated that the focus is more often primary in the synovial membrane. Stiles[7] has stated that in probably one-half of his cases in children the disease was primary in the synovial membrane. Certainly in our experience it would seem that the majority of cases are primary in the synovial membrane; but this opinion is based principally on clinical and radiographic studies.

All of the cases in this series were unilateral. Some patients had tuberculosis of the lungs when operated on. Definite figures are not possible, for, while many cases were classified as suspicious, only six were proved to be phthisis. One patient whose case was considered suspicious died, and two other deaths occurred three or four years later in patients whose lungs were clearly tuberculous at the time of operation. All were benefited by the operation. Two patients operated on are not in good health owing to kidney-lesions, but the condition of their knees is one of bony ankylosis, and the cases are classified among the successful cases. One patient with undoubted tuberculosis of the lungs has gained 35 pounds and reports himself in the best of health. We do not hesitate to do a resection of a tuberculous knee when it is one of two or three foci and seems to be the chief cause of the patient's poor general condition. Ordinarily, the patient's finances prevent indefinite treatment by rest and special apparatus. Our object must be to enable these people to get about without pain.

The types of operations suggested for tuberculosis of the knee-joint vary all the way from an erosion to a complete excision. In this study resection only is considered.

Ely in the last few years has made a point that the disease in the joint is there because the soil is favorable to the growth of the tubercle bacilli and that all that is necessary is to change the soil to starve out the bacilli. Therefore, he advises removal of only enough of the joint-surface to produce an ankylosis, doing this by aid of a chisel without disturbing the crucial ligaments or spreading wide the joint. The soft tissue may be ignored. The ankylosis changes the spongy bone to hard bone.

The Fergusson[8] type of operation is used in the Mayo Clinic and is essentially as follows: A tourniquet is applied 6 inches above the knee; an incision is made two-thirds the circumference of the knee following the line of the joint and running just below the patella, severing the lateral ligaments and the ligamentum patella, allowing quick exposure. The leg and foot are wrapped with sterile towels so that the knee may be acutely flexed on the thigh. The soft tissues are dissected back three-fourths of an inch from the head of the tibia and the femur. If the patella is fixed or seems involved, it is removed. An amputation saw with a blade from 3 inches to 4 inches wide is used to saw off the top of the tibia and femur, usually removing about ½ inch of the tibia and from ½ to ¾ inch of the femur. By a little care the saw may be introduced at such an angle as to insure the accurate fitting of the ends of the bone at the angle desired. If the patient's business requires much standing, about 10 degrees flexion is desirable, but for those who remain seated much of the time from 15 to 20 degrees flexion is a better position. The denuded surfaces are swabbed with iodin, the soft tissues sutured together with chromicized catgut and a rubber drain inserted. Such soft tissue is removed as may be superfluous in closing the wound. An extensive dissection for removal of all the soft tissue showing involvement is not necessary or desirable. Through a separate incision in the skin a wire nail is driven up through the head of the tibia into the femur. The nailhead is left projecting out through the skin, whence it is very easily removed in two or three weeks. It serves its main purpose while the dressing is being applied and in this differs from the use of metal plates as advocated recently by Osgood.[9] The tourniquet is removed and the skin is sutured with silkworm and horsehair, and the leg is then put up in a plaster-of-Paris case including the ankle and foot. At the same time a window is cut over the wound; within forty-eight hours the dressing is changed and the drain removed. Naturally there is some pain, which usually ceases within forty-eight hours, and, once fibrous union has started, the convalescence is free from pain. The case, together with the suture and nail, is removed in about two weeks and a new case applied which remains from six weeks to three or four months. When the ankylosis seems firm enough, a stiff-legged brace is used by day and a light posterior splint at night. Some of our patients have had sufficiently firm union to bear their weight in four months, but usually it takes about a year (Fig. 4).

[8] Fergusson: Tuberculosis of Bones and Joints, Senn, 1892, p. 456.

A review of our work has led us to advise the operation in all cases of proved tuberculosis of the knee even if but slight destruction of bone has been revealed by the Roentgen ray. On opening up a joint in which the radiogram has shown but slight destruction of bone, one is often surprised to find complete destruction of the articular surfaces. In none of our cases of this type has there been bony ankylosis demonstrable on exposure of the joint at operation.

ABSTRACT OF DISCUSSION

Dr. Edgar D. Oppenheimer, New York: When there is marked flexion deformity and this is straightened, we may expect gangrene of the blood-vessels; but we had one case in which no such condition was present. The leg was practically straight before operation; and the day following, occlusion of the veins took place. I have seen no other case reported in which this occurred, when no straightening of the leg was done. I dissected the leg afterward and found the arteries patent; but the veins were occluded above the site of operation. There seemed to have been no accident, and I believe it was due to disease and inflammation about the vessels in the popliteal space. I would suggest that we make a longitudinal incision, instead of a cross incision; because the latter cuts off so many collateral veins.

Dr. W. C. Campbell, Memphis, Tenn.: I was a little surprised to hear Dr. Henderson state that he removed as much as three-quarters of an inch, I believe, from each surface. That seems a considerable amount and more than I have been in the habit of removing. I take off as little as possible. I just remove the cartilage and expose the bone, so that the surfaces will fit snugly. I have had no displacement, and have not had to use a nail or a plate in my work. The cast is applied with very little padding, and has been sufficient to give proper immobilization so that ankylosis was the result.

Dr. John Ridlon, Chicago: Did I understand Dr. Henderson to say that he and his associates in the Mayo clinic advise excision of all tuberculous knee-joints in adults and children? It seems to me that we should not go on record with such a recommendation. Men who treat tuberculous knee-joints by conservative methods, know that many knees are saved with perfectly good joints; whereas, excision or amputation would be done by many general surgeons. I have had the satisfaction of saving the knee in a case in which a good surgeon had excised one knee and wished to excise the other. The patient objected. The other knee, which was not excised is now straight in extension, has normal flexion, and has been for ten years a sound and healthy knee. At the meeting of the American Orthopedic Association in Philadelphia, Dr. Ryerson said that he wanted to see such a case. When he gets back to Chicago, I will send this woman to see him. It is by no means necessary, in my opinion, no matter how great the destruction, to excise the knee in order to cure the disease. As a time-saving measure in adults, it may be desirable; but for this reason, in children it is not. I saw a case in which an eminent orthopedist had made excision in childhood, and in adult life; there were 9 inches of shortening. I do not wish this Section to go on record as favoring excision in all cases of tuberculous knees.

Dr. R. A. Hibbs, New York: Is it not probable that the good accomplished by the resection of the knee for tuberculosis, is due to the elimination of motion produced by this operation, rather than to the removal of the tuberculous infection? The relief of symptoms occurs, as a rule, only in those cases in which motion is eliminated by a fusion taking place between the femur and the tibia. When this fusion does not take place, the activity of the disease usually continues. If such is the case, since it is impossible to remove all the infected material, it would seem to be wiser to make no attempt to remove it at all, confining the operative procedure to one which will best insure the desired fusion. As a means to this end, therefore, it has been my custom simply to remove the cartilage of the two bones and implant the denuded patella between them.

Dr. Fred. J. Gaenslen, Milwaukee, Wis.: I am glad that Dr. Hibbs brought up the question of the purpose of the operation. He, I think, agrees entirely with Dr. Ely that in all operations for the treatment of tuberculous conditions of joints, the elimination of motion is the essential thing. In all text-books on surgery, we read of the necessity of eradicating every possible trace of tuberculosis in a joint, when the operation is indicated at all. I have not had much experience in resections of tuberculous joints, and they are rarely called for with the efficient present-day conservative methods, but I have resected some knees and shoulders, and I was sure, at the end of these operations, that there was some tuberculous tissue that I had not touched, especially in the case of a shoulder, where it is hard to get at the synovial membrane around the glenoid cavity and to remove the granulation tissue in the cavity. Therefore I would say that the eradication of all tuberculous tissue in a tuberculous joint is next to impossible; and I have never seen any one else do a complete operation on any joint. In adults, tuberculosis of joints is often associated with pulmonary infection, in which case general anesthesia may be undesirable. In a recent case of knee-joint tuberculosis with pulmonary lesion, resection was done, using Bier's method of local anesthesia. The limb was first rendered bloodless by means of a rubber compression bandage from the toes to midthigh. The saphenous vein was exposed in the lower third of the thigh between two Esmarch bandages and 100 c.c. of 0.5 per cent. novocain solution were injected into the vein. Complete anesthesia resulted very promptly, so that the resection was absolutely painless. Just prior to closing, the Esmarch bandage was removed and as the last skin sutures were taken sensation was just returning. The method appears to deserve wider application.

---

[9] Osgood: Boston Med. and Surg. Jour., July 24, 1913, p. 109.

Dr. Fred H. Albee, New York: The attempt to remove all tuberculous bone at the knee-joint is inadvisable, because it jeopardizes our chances for bony union. We should remove as little bone as possible, and thus get the largest possible surfaces of the tibia and femur together. I believe that the whole object should be to get bony union. I have never seen a knee-joint in which bony union had occurred, in which any tuberculous tissue remained for any length of time. The question is: Can we, in any way, aid in hastening this bony union? Dr. Hibbs has already mentioned his method of putting in the patella. I believe that every effort should be made to hasten bony union. I have carried out the following procedure in a few cases in which the patella was a little involved. I took off a small portion of the posterior part of the patella, and split the remaining portion into two strips. I then inlaid these inserts into each side of the tibia and femur, putting half in each bone. In the three cases in which I have done this, the bones united rapidly. In another case, I used a graft from the tibia with the same technic. Dr. Osgood, a year ago, in a case of excision, came to the conclusion that a Lane plate was advisable in order to get more rapid bony union; and I understand that the orthopedic surgeon at the Massachusetts General Hospital has been using the Lane plate since. I believe it is a good thing to put in bone instead of a Lane plate; and that the inlay is preferable in hastening ankylosis. Within a month I have seen a case of tuberculosis which had all subsided. I had done a circular cutting, taking off only cartilage from the tibia and femur and getting the broadest contact of bone. Nevertheless, the patient had two or three degrees of motion, and an unstable and sensitive joint. If I had put in inlays, I think he would have got union. In another case in which I did a resection a few years ago, the patient was later taken to another hospital and on account of delayed union amputation was done there. I believe there would have been a good chance for union in this case if time had been given for it; but there are a large number of cases of delayed union in which a secondary resection has to be done.

Dr. John Dunlop, Washington, D. C.: How soon after the diagnosis is made is this operation advisable?

Dr. H. W. Orr, Lincoln, Neb.: When a nail is not used, or, perhaps, when a nail is used, would it not be better to have the plaster put on up to the trunk, so as to get real immobilization?

Dr. Emil S. Geist, Minneapolis: One point that has not been brought out concerns the question of late deformity after this operation. Many of us have seen resected knees in which a good deal of deformity has taken place, usually in the direction of flexion. I have seen one case in which, following resection, there was a right-angle deformity, a genu recurvatum. The Germans believe that there is a tendency to deformity for a long time after such a knee has been resected even if bony ankylosis supervened shortly after resection, and I think that a mistake was made by many of us in not holding the knee in proper position long enough, either by means of braces or with plaster appliances. This is an important point.

Dr. Samuel F. Jones, Denver: Three distinct points should be strongly emphasized. In cases of tuberculosis of the knee-joint in adults, as Dr. Ridlon has well said, it is known that conservative treatment will enable a large number of patients to recover, if the proper immobilization is carried on through a sufficient period of time. Secondly, we should go on record as absolutely condemning the resection of any tuberculous joint in children. Thirdly, amputation should be advised and instigated as a life-saving measure only in cases of extensive tuberculous joint-disease.

Dr. Leonard W. Ely, San Francisco: I shall first refer to the point that Dr. Hibbs brought out, as to why, if we resect, we do not dissect out all tuberculous material. The reason for this rests on evidence that is not, I think, absolutely conclusive. It rests, first, on the statement made by many operators that if they resected these joints, they got the same results, whether they removed much tissue or very little, or whether they performed the operation devised by Flint, a very thorough operation, and removed 3 or 4 inches of the bone. No matter which one of these methods was pursued, the result was the same, namely, a cure, provided secondary infection was avoided. It rests, secondly, on the fact that there is no known way of removing all the tuberculous tissue. No one can be sure, when he closes a wound, no matter how he has operated, that he has absolutely removed all of the diseased tissue. It rests, thirdly, on an assumption of what takes place in the joint after resection, that is, in the tissues, in and about that joint. We do not know exactly what these changes are. No one has proved them. They have been said, on good authority, to be a disappearance of the essential tissues of the joint—a disappearance of the red bone-marrow, and a disappearance of the synovial membrane. I have never seen any absolute proof of this but I believe it is true from considerable evidence in my possession as well as from evidence submitted by others. Now Mr. Fraser tells us that it is absolutely erroneous, and that red marrow, instead of being a favorable soil for tuberculosis, is an absolute bar to its occurrence. I should say that the result is probably dependent on a complete deprivation of motion. We have assumed that it was due to bony ankylosis, but bony ankylosis certainly does not take place immediately. Therefore, we are driven to the theory that it is a fibrous condition of the marrow which takes place, producing a fibrous, and, eventually, a bony union; but here again, Mr. Fraser says that fibrous marrow is a favorable seat for tuberculosis. Again we are driven to the opinion that this operation of resection, if there is no secondary infection, does cause a complete disappearance of tuberculosis at that spot.

Dr. J. D. Griffith, Kansas City, Mo.: In 1871, 2 and 3, when I was an intern in Bellevue Hospital, New York, in the cases there in which amputation was performed, death as a rule occurred. We always tried to get "laudable pus;" if we did not, we wondered why. We pulled our silk ligature out of our buttonholes. We did not know that these cases were tuberculosis at that time; but Dr. Ridlon and one or two others may remember, that the patients that were cured in Bellevue Hospital were the ones that came in with old sinuses, whose history ran over a series of years. Dr. J. R. Wood used to excise these joints right along, and these were the big operative cases with recovery. The patients recovered in the same percentage as they do now. There was plenty of laudable pus coming from the joints. We put them up in plaster of Paris spicas with big openings on the side. We kept the wounds well dressed and fed the patients up; and the results of the excisions did not vary very much in these cases from those in similar cases now. This is a matter of history.

Dr. Albert H. Freiberg, Cincinnati: It seems to me that we are liable to render ourselves guilty of too easy and too wide-spread a generalization on the subject of the removal of infected tissue in tuberculosis of the joints. It does not complicate the operation greatly to remove all the tissue that is obviously infected, and I do not see any great objection to doing so. On the other hand, there is not the best of clinical evidence that an ankylosis is required in order to obtain complete cure; and that it is a matter of comparatively little importance whether or not tuberculous tissue remains behind. I am sure that members of this Section can recollect cases of excision of the knee for tuberculosis in which non-union resulted and in which there was no recurrence of tuberculous disease. I have had such cases in my own experience, although not for some years. We need to go back to the pathology of tuberculosis and nature's methods of curing the disease in order to find out what we had best do. If we leave material obviously affected with tuberculosis, in the joint at the site of operation, it must become encapsulated by means of fibrous material and rendered innocuous in that way, be carried off by means of the circulation or the lymphatics, or else come to the surface by means of a continuous breaking down of tissue. The more infected material we take away, the less there is to be disposed of by the tissues in one of these three methods. While an encapsulated tuberculous mass may be harmless to the end, it nevertheless, remains a potential source of harm. Dr. Henderson gave an instance in which tuberculous material, which at first gave no trouble, finally broke down and caused a sinus in a knee which was ankylotic. In this case, although ankylosis resulted, the sinus persisted and led to final amputation of the limb. I do not mean that by removing all infected material we always dispose of this danger, but we may do so sometimes. However much we may feel, on theoretic grounds, that the material will be taken care of, there is the danger that sometimes it will not; and therefore it had better be removed.

Dr. M. S. Henderson, Rochester, Minn.: As regards gangrene, I must say that I have never seen it, but would merely suggest that if a tourniquet was used for any length of time it might have been the cause. Dr. Campbell speaks of saving as much bone as possible to prevent shortening. My experience is that a patient with a stiff knee gets about better with from an inch to an inch and a half of shortening than if the leg is the same length as the normal one. Dr. Ridlon advises against resection of tuberculous knees in children and with this I am entirely in accord. In my paper I am talking only of tuberculosis in adults showing bony destruction. Dr. Hibbs made the point that the elimination of motion is probably the cause of the eradication of the disease and should be thought the factor rather than the extensive removal of bone. This is true to a certain degree, but I feel that bony ankylosis should be obtained. Tuberculosis is seen in the shaft but very rarely, whereas it occurs more often in the metaphysis and epiphysis. By attaining bony ankylosis we change the soft bone to hard bone and the disease is cured. I might mention a patient whom I saw, a woman who had had a resection for tuberculosis 25 years ago in Germany. We took a roentgenogram and found the medullary cavity of the femur to be directly continuous with the medullary cavity of the tibia and that we had practically one bone instead of two. I have not used the patella in this class of cases, as suggested by Dr. Hibbs. It is a splendid means of obtaining an ankylosis when it is wanted in infantile paralysis cases, but in a tuberculous knee-joint would not cause what seems to me important—a bony ankylosis, nor would it assist nature by removing the bulk of the tuberculous disease. In the resection of a knee-joint for tuberculosis, we save the patella, whenever possible, for, if it is healthy, its removal will result in considerable trauma and cause healthy tissue to be opened. If the patella is diseased, it cannot be used and, if bone is removed from the tibia and femur, the patella is not necessary in the ankylosis. I have not used local anesthesia in resections, but think that it would be a help in certain cases. We use a light ether anesthesia in patients having tuberculosis of the lungs and have not had any bad results. Dr. Albee mentioned the use of the Lane plate by Osgood. All our patients here reported were operated on previous to March, 1913, before Osgood's results were published. It is true that union is sometimes slow. Experimental work has shown that eighty-three days is the earliest time in which bony union could be demonstrated in closed fractures in animals and it usually took from one hundred and fifty to one hundred and seventy-five days.

A Museum of Fatigue-Eliminating Devices.—In Providence, R. I., a museum of devices for the elimination of unnecessary fatigue has been started (Gilbreth, F. B.: *Scient. Am.*, Nov. 14, 1914). It emphasizes the paucity of such devices for, in spite of the fact that tens of thousands of letters requesting cooperation were sent out and replies indicating willingness to cooperate were received, the museum contains at present only six simple devices, chiefly various types of chairs. One device permits work which has always been done standing to be done sitting. Another device permits the worker to stand part of the time at work which usually had been done sitting. Another type eliminates vibrations from the floor. This is said to have been very successful.—*Scientific American.*

THE BACTERIOLOGIC EXAMINATION OF THE URINE IN A CASE OF ECLAMPSIA *

G. F. DICK, M.D.
AND
G. R. DICK, M.D.
CHICAGO

Recently we[1] published the results of the bacteriologic examination of the urine in parenchymatous nephritis. The frequency of renal lesions in eclampsia suggested the bacteriologic examination of the urine in this trouble.

According to Williams[2] the infectious theory of eclampsia was advanced as early as 1885, and various bacteria have been cultivated from the urine and also from the tissues and juices of the body. Other investigators, however, failed to confirm these findings and Williams states that his own investigations have given negative results. It seemed desirable, however, to examine the urine of eclampsia by the newer cultural methods, which had yielded positive results in nephritis.

The patient from whom the urine was obtained was a woman 30 years old who was admitted to the obstetric ward of Cook County Hospital during the night of September 15, 1914. The patient was in convulsions when admitted, and a forceps delivery was made during the night. When seen at 10 a. m. the following day she was still in coma and showed marked edema of the face and extremities. Since admission she had voided 3 ounces of urine. She died about twenty hours after delivery. With aseptic precautions a specimen of urine was obtained by catheter. It measured 15 c.c., was turbid and smoky and contained a large amount of albumin, with numerous coarsely-granular casts, many red blood cells, some polymorphonuclears, spherical pear-shaped and tailed epithelial cells.

Aerobic cultures on blood-ascites-agar showed no growth. Anaerobic cultures on the same medium and dextrose-agar shake cultures showed many slowly-growing colonies which were visible on the third day. They consisted of gram-negative bacilli about the size of influenza organisms. They grew anaerobically only, forming pin-point, transparent colonies on blood-agar without affecting the blood. In twenty-four hour cultures they were sluggishly motile. Satisfactory growths on the ordinary mediums were not obtained.

The intravenous injection of the organisms from ten blood-agar slants produced no apparent result in a small dog.

In one of the agar shake cultures there developed a single colony of gram-positive short chained streptococci which did not grow in transfer.

Similar cultures of catheterized specimens of urine from normal puerperal women gave in one case entirely negative results; in a second case a few colonies of staphylococcus.

Little can be said concerning the significance of the organisms described. We have, however, found in a number of nephritic urines organisms resembling those cultivated from the urine of the case of eclampsia and it seems to us that the results described indicate that the infectious theory of eclampsia is still worthy of consideration.

REPORT OF A CASE OF ACUTE DILATATION OF THE STOMACH

ANTONIO MAYORAL, Jr., M.D.
PONCE, P. R.

In a case of double pyosalpinx the patient suffered an acute dilatation of the stomach during the operation, so that it could be seen and examined. The case is of special interest, first, because it cannot be explained by the most common theory of the cause of this condition, that is, constriction at the lower end of the duodenum between the root of the mesentery and the vertebral column by the dragging down of the small intestine; second, because it occurred in the midst of the operation and not as a postoperative complication, and third, because the patient completely recovered with only slight discomfort in the epigastrium for the next twenty-four hours.

History.—P. C., a mulatto girl aged 21, not married, with no tuberculosis or cancer in the family, with syphilitic marks on the arms, upper abdomen and legs, came to me because of profuse bleeding at menstrual periods, a white discharge and pain in the left iliac fossa. Vaginal examination revealed a creamy discharge from the cervix of six or eight months' duration. The cervix was eroded. The uterus was not very movable. A tender mass the size of a hen's egg could be easily felt on the left side.

Operation.—Under ether anesthesia, dilatation and curettage were done. The patient was placed in the Trendelenburg position, the abdomen painted with 7 per cent. tincture of iodin and washed with alcohol, and a 3-inch incision made in the median line, between the umbilicus and the symphysis pubis. The peritoneum was opened between forceps. Extensive pelvic inflammation was found; both tubes were attached by fresh adhesions to the surrounding structures. Without much trouble the right tube was freed and amputated by clamp and ligatures of No. 2 catgut. The left tube was somewhat more adherent, but it was finally freed, and after having ligated the tube as it leaves the uterus and the free edge of the broad ligament just under the tube, and as I was about to place my clamp to amputate it, the patient began to act queerly, the respiration quickened, the pulse became rapid and thready, and the intestines came out of the wound and were held back with difficulty. I continued the operation as well as I could, and in placing my hand into the wound was surprised to find the stomach at the upper edge of my incision and a second later about three fingers breadth from the symphysis pubis. The stomach tube was ordered passed and a good quantity of gas was let out; the stomach gradually returned to its normal size, but no. liquid was obtained. Anesthesia was then stopped and the operation was rapidly finished, continuous catgut sutures being used for closing. The table was lowered to the horizontal position, and the patient dressed and sent to the ward. Recovery was uneventful.

The patient was anesthetized by our special anesthetist, a nurse of large experience. The case from the beginning was hard to manage and so rigid that I had to call for deeper anesthesia continuously, the patient not becoming fully relaxed until shortly before she developed the dilatation of the stomach.

The causes of acute dilatation of the stomach are given as: First, constriction of the lower end of the duodenum between the root of the mesentery and the vertebral column by dragging down of the small intestine (Albrecht). It is obvious that in this case such a constriction could not have occurred, as the patient was in the Trendelenburg position when she developed the dilatation, and the intestines were thrown toward the diaphragm. Second, excessive secretion and paralysis from overdistention (Fagge). In this case, nothing but gas was let out of the stomach, there was no excessive secretion. Third, infarction, peritonitis, dilatation as a part of general involvement of the intestines (P. Muller). But there was no general peritonitis in this case. What then was the cause of the dilatation? I believe that in this case at least we must look for the cause, first, in a paralysis of the stomach center in the brain due to the anesthesia that had to be pushed to its limit, as the patient could not be relaxed otherwise; and second, to the rapid development of gases within the organ, a thing favored by the paralysis of its wall.

QUININ SALTS IN POSTOPERATIVE CASES

PRELIMINARY REPORT

EDMOND BONNOT, A.M., M.S., M.D.
ST. LOUIS

The method originated with me accidently in May, 1914. After operating for acute appendicitis on two malarial patients I instructed the nurse to give the patients 10 grains of quinin muriate by rectum every six hours until such time as the patient could take quinin by mouth. To my surprise these patients had no nausea, vomiting, gas pains, backache or postoperative thirst. The result was so marked that I have used it in all laparotomies since, with the following results in twenty cases including the various abdominal operations:

No nausea or vomiting in 10 cases.
Slight nausea and vomiting in 6 cases.
Much nausea and vomiting in 4 cases.
No gas pain in 19 cases.
Slight gas pain in 1 case.
No backache in 20 cases.
No desire for water within the first twelve hours in 9 cases.
Only moderate thirst in 11 cases.

In all cases the postoperative thirst was much retarded.

Dr. Willis Young of St. Louis has since used this method in all his laparotomies with corresponding results.

The Sisters at St. Anthony's Hospital have been so impressed with this method that they have used it as a routine postoperative procedure in more than one hundred cases with only one case in which there seemed to be no benefit.

The technic is simple: Quinin muriate, 10 grains, dissolved in 2 ounces of water at 100 F. is given by rectum immediately after operation, followed by saline proctoclysis or (in septic cases) by 6 ounces of olive oil. The quinin is repeated every six hours for four doses. If after the quinin is stopped the patient shows any signs of gas pains or backache, another dose will give immediate relief.

I use the muriate of quinin because of its solubility; but any salt of quinin will answer. Dr. Willis Young reports that he has used the sulphate in suspension with equally good results.

So far I have not had any idiosyncrasy to quinin in this method or noticed any bad effect. In two cases of pregnant women who were operated on for acute appendicitis I did not use the quinin, and both suffered much with gas pain. Whether or not quinin would have been contra-indicated in these cases I do not know.

In all cases recorded, ether was used as the anesthetic. I do not attempt to explain the action of quinin in this relation except from its analgesic effect and the prevention of the temporary postanesthetic paralysis of the intestines.

3329 Park Avenue.

Special Article

PRACTICAL PHARMACOLOGY *

INTRODUCTORY

Under the title given above it is proposed to publish a series of articles in which there will be discussed the materia medica, pharmacology[1] and chief therapeutic uses of those drugs which have been accepted by the Council on Pharmacy and Chemistry for inclusion in the "Handbook of Useful Drugs."[2] Convenient forms for prescribing them will be suggested and the advantages of depending on standard drugs rather than on commercially exploited nostrums will be demonstrated.

Several years ago THE JOURNAL published a somewhat similar series of articles under the title "The Pharmacopeia and the Physician," and while the same general plan will be followed in the present series, the discussions will be limited almost entirely to the really essential drugs of the materia medica, as indicated in the title of the articles.

It is evident that the therapeutic use of drugs requires some knowledge of their pharmacologic actions, but many physicians fail to appreciate the true value of pharmacology. Frequently, too, it is impossible to distinguish the literature of the disinterested investigator from that issued by those who are commercially interested in the products which they discuss. It is hoped that in these articles we may be able to present the essentials of the pharmacology and therapeutics of the important drugs so that they may be useful to the general practitioner who has not the time and the hospital facilities for clinical research.

We trust that this treatment of the subject, so far from satisfying the reader, may stimulate him to further inquiry and the use of the larger works on pharmacology and therapeutics.

The pharmacology of the different drugs will be discussed very briefly in some cases, somewhat more comprehensively in others, but sufficiently in each case to afford a basis for the best therapeutic use of the drug under consideration. The discussion of quinin and digitalis, respectively, illustrates the principle followed. Quinin finds its greatest use in the treatment of malaria, in which its value depends on its killing the organisms which are found in the blood, and the secret of the successful employment of quinin is to get the requisite amount in the blood at the proper time; hence dosage and methods of administration are of greater importance in that case than a knowledge of the various other pharmacologic actions of quinin, beyond the mere fact that it is a general protoplasm poison, which is consequently injurious to all tissues with which it comes in contact in sufficient concentration. Digitalis, on the other hand, does more harm than good in the hands of those who use it without a pretty accurate knowledge of its pharmacologic actions; it becomes necessary, therefore, to devote more attention to the pharmacology of digitalis than to that of quinin.

Drugs produce their effects by increasing or decreasing the normal functions of the structures on which they act, and in so doing they do not themselves produce an appreciable amount of energy. The failure of a drug to produce its expected therapeutic effects may often be explained by the condition of the organ on which it acts. A grasp of this relationship between drugs and the organism will serve to simplify the understanding of their uses and limitations, and will prevent frequent disappointment.

Every drug exerts a variety of actions, but only a few of the actions of any drug are of benefit in any given condition; the others are negligible or detrimental. Thus, in the treatment of night sweats, atropin is used on account of only one of its many actions, namely, its power of limiting secretion.

The therapeutic usefulness of a drug depends on the fact that it exerts a far greater action on certain organs or tissues than on others. Strychnin, for example, is capable of combining with certain cells in the central nervous system and affecting them profoundly, while leaving the other cells of the body practically unaffected.

The influences of age, sex, weight, diet and many other factors which modify the actions of drugs are generally recognized and do not call for detailed discussion here, but every physician encounters occasional disappointment in the use of a drug on which he has come to rely, and we shall point out some of the most common causes of the variability of action, which are frequently overlooked because they are deemed of too little importance to merit careful consideration.

ABSORPTION AND ELIMINATION

The intensity of the action of a given drug usually depends largely on the total amount which acts at one time. Hence, the action of those which are absorbed into the circulation depends on the amount in the blood at one time, which is determined to some extent by the ratio between the rate of absorption on the one hand and that of elimination or destruction in the body on the other. A large dose of a drug may produce less effect at one time than a small dose administered in the same way at another time, the difference in the intensity of action being due to differences in the rates of absorption and elimination. The intensity of action may be influenced in other ways.

The degree of dilution in which a salt is administered not only influences the intensity of a given action, but may even determine its nature. A concentrated solution of magnesium sulphate may cause nausea, whereas the same amount of the salt in dilute solution will cause purgation. Magnesium sulphate usually causes only watery diarrhea when it is administered properly, but it has been known to cause death when administered in the usual way, because of its rapid absorption and slow elimination.

A common cause of disappointment is the want of exact knowledge concerning the absorption of drugs. It is often asserted, and accepted without question, that because a given substance is very soluble in water, it must necessarily be absorbed readily from the alimentary canal. Disregarding the relatively slow absorption of soluble purgative salts, we may call attention to the fact that for some unknown reason,

---

* This is the first of a series of articles on useful drugs—on practical pharmacology for the general practitioner. As soon as completed, these articles, elaborated by additional subjects, will be published in book form.

[1] The terms "materia medica" and "pharmacology" are often somewhat loosely used. Materia medica treats of the physical and chemical properties of drugs and of their pharmaceutical preparations. Pharmacology, or pharmacodynamics, treats of the actions which drugs exert on normal animal tissues or organs. For example, the paralysis of vagus endings in the heart by atropin is one of its pharmacologic actions.

[2] The Council has made a careful selection of all drugs and preparations, irrespective of their nature, whether official or unofficial, proprietary or non-proprietary, which seem to be the best for the treatment of diseases, and these have been included in the little volume entitled, "A Handbook of Useful Drugs."

some of the *very* soluble glucosids are absorbed slowly and irregularly from the gastro-intestinal tract; also that certain glucosids or resins which are wholly insoluble in water are absorbed fairly rapidly from the gastro-intestinal tract. In other words, we must recognize the fact that every drug is a law unto itself in regard to its rates of absorption and elimination.

Most drugs are not absorbed readily from the stomach, but must pass into the duodenum before absorption begins; it may follow, therefore, that when the gastric movements are interfered with by disease or drugs, and especially when the pylorus remains in tonic contraction, as it does at times after large doses of morphin have been taken, drugs may remain unabsorbed in the stomach for hours after oral administration. Drugs should be administered subcutaneously or by the rectum when it is suspected that the gastric contents will be prevented from passing into the duodenum in the usual manner.

Comparatively few drugs are absorbed from the unbroken skin, and the use of ointments and plasters containing active alkaloids is irrational in the main; the good results which may follow their use in most instances are not due to the alkaloids. For example, in the case of opium and lead wash — a most unscientific mixture, since the morphin in that case is valueless — the beneficial results are due to the astringent action of the lead wash. A few substances which are readily miscible with oils and fats penetrate the skin sufficiently to act on the sensory nerve-endings, but our knowledge of this subject is far from complete.

Another cause of disappointment lies in the fact that physicians sometimes forget that locally acting drugs may fail to exert an effect after absorption similar to that observed in the alimentary canal. Tannin, for example, acts as an astringent on the mucous membrane of the gastro-intestinal tract after its oral administration, but it is not absorbed in the free state and does not exert such an action on other parts of the body. Antiseptics are still sometimes recommended for their action on micro-organisms in the circulating blood, but such misleading advice occurs chiefly in "interested" literature.

We are not so well informed as we should be even on the subject of dosage; it is often stated as a rule that the oral dose of a given drug is about twice as large as the subcutaneous dose, and that the rectal is about twice the oral. These ratios apply to very few drugs indeed; the attempt to regulate the dosage of some drugs by this rule would result disastrously. In fact, death has resulted from the subcutaneous injection of an amount of strophanthin equal to one-half of the oral dose. This illustrates the necessity for a better acquaintance with a few drugs, rather than a superficial knowledge of a large number. At best drugs are like two-edged swords capable of doing harm if used improperly, and if we assume the responsibility of using them we owe it to our patients to know as much as possible about their actions.

SYNERGISTIC ACTIONS

It was formerly customary to use mixtures of many drugs having supposedly related actions without any clear idea of their synergistic effects, but such mixtures are not used at present by educated physicians, for we are coming to have a better understanding of the synergistic actions of drugs which are useful in some cases and harmful in others. Some of these synergistic actions will be discussed when we consider the drugs exhibiting them.

MODES OF ADMINISTRATION

Unless the oral method is contra-indicated, drugs should be administered by the mouth. While the other methods advocated from time to time may be suitable for special cases, and in the hands of those who have developed a special technic, the oral administration will suffice in the vast majority of cases.

The intravenous injection of a variety of drugs has been advised, but this method is distinctly dangerous in the hands of any one who is not skilled in its use, and it is often disappointing even with the best technic.

Compressed tablets of insoluble drugs do not always disintegrate rapidly in the stomach, and such drugs are preferably given in the form of mixtures or as dry powders, which may be enclosed in capsules. Many of the ready-made pills tend to become harder and less readily disintegrated when long kept. Freely soluble salts, such as potassium bromid, taken in doses of 0.3 gm. (5 grains) or more, may give rise to gastric irritation with nausea, when they are administered in concentrated solution, or in the form of compressed tablets, which form concentrated solutions on dissolving in the stomach. Such salts should be dissolved and mixed with from ten to thirty times their weight of fluid before being administered.

Nausea and vomiting sometimes follow the administration of various drugs. When this symptom arises from local irritation of the stomach it may be avoided either by dilution or by a different mode of administration. In other cases, as in members of the digitalis group, the nausea and vomiting, being due to a stimulation of the vomiting center in the medulla, are not influenced by the mode of administration. In such cases, nausea is to be avoided only by regulation of the dose. Before resorting to inconvenient methods of administration, therefore, one should be certain that the method proposed will actually give relief from the disagreeable symptom.

Idiosyncrasy, tolerance and cumulation, so called, will be discussed in connection with those drugs in the use of which they are important factors.

MULTIPLICATION OF PREPARATIONS

The present era of pharmacy and therapeutics is marked by the multiplicity of alleged remedies urged on the attention of the prescriber. This multiplication of preparations is attributable largely to the influence of commercial interests, which have often had more weight than considerations of pharmacologic and medical science and have overshadowed the interests of the sick.

In this confusion physicians will often find themselves at a loss how to choose wisely the most efficient agent. A careful study of the new remedies offered will show that few present any new therapeutic action or are specifics for particular diseases. Most of those which are worthy of consideration claim advantage over the older remedies in the avoidance of disagreeable side effects. In a considerable number of cases these claims have not been realized and the remedies are needless encumbrances to our materia medica. Before accepting a manufacturer's claim that his preparation is preferable because it avoids undesirable by-effects, one should make sure that this freedom from disagreeable effects is not accompanied by lack of therapeutic efficiency.

In choosing remedies the practitioner will gladly welcome the help extended by the Council on Pharmacy and Chemistry in sifting the mass of evidence and selecting for regular use the remedies listed in the new volume, "Useful Drugs." In admitting preparations to the book New and Nonofficial Remedies, the Council has adopted a liberal policy; it has admitted any drug which has probable value if exploited in an unobjectionable manner. Though the Council has been in existence for nearly ten years and though during that time manufacturers have been afforded ample opportunities for submitting evidence of any advantages which their preparations possess, among the thousands of these advertised to physicians, not more than 340 are enumerated in New and Nonofficial Remedies, and of this number not more than a score have been found of sufficient importance to merit inclusion in the "Handbook of Useful Drugs," for admission to which evidence of merit is essential.

It is obviously impossible in these articles to discuss any considerable number of the popular nostrums. A few of them, however, will be mentioned, chiefly to show the methods of misrepresentation employed, and the necessity of fostering the use of standard drugs of proved value and well-known side actions for which proper allowance may be made in the administration.

These side actions deserve more attention than they usually receive. We have been prone to consider unfavorable symptoms in patients as unavoidable manifestations of the diseases from which they suffer in many cases in which the drugs were contributing causes at least. We must face the question squarely and recognize the fact that there is no such thing as an ideal drug. When a manufacturer asserts that his preparation possesses all the advantages of a given drug with none of its disadvantages, his excessive optimism is obvious.

CLASSIFICATIONS OF DRUGS

Buchheim classified drugs about sixty years ago according to their more prominent pharmacologic actions, and this classification has been retained with some modifications to the present time, despite the fact that it has many disadvantages. No strict classification is possible, because every drug has a variety of actions, and no two have exactly the same range of activities.

We shall make no effort to group the drugs in any rigid way in the following series of articles, and it is understood that any grouping attempted is merely suggestive and intended to facilitate the convenient discussion of the various drugs. The following examples will serve to illustrate the disadvantages of attempting a too rigid adherence to any classification: The convulsions produced in frogs by strychnin, morphin, thebain and some other drugs are identical in character; yet in view of their clinical use, it would not be desirable to place strychnin and morphin in the same class; atropin and morphin are antagonistic in small doses and synergistic in large. The local anesthetics, the general anesthetics and some other groups, on the other hand, present no such difficulties of classification.

XV

Treatment

The preventive measures have already been referred to and described. They consist of proper bathing to keep the skin in good condition; proper clothing, depending on the region, season and exposure; proper heating and ventilation of living rooms, bedrooms and buildings in which persons are employed, and in the case of the child, proper heating and ventilation of the schoolrooms. As previously stated, a child may be overclothed for play, as well as underclothed for sitting in cool rooms. The child should be extra well clothed, if he attends an open-air or open-window school during the cold seasons; such schools probably are among the greatest means of prevention of coryza, sore throats and coughs. On the other hand, the too severe exposure of young children and babies to dampness and winds is inexcusable and does not increase their resistance against catching cold, and often precipitates more serious conditions. Any person who has a tendency to nasal or pharyngeal colds should not suffer undue exposure at night. Too many windows being open may cause too much direct draft over the face. Fresh-air sleeping should be governed by common sense. Cold daily sponging of the child's face, neck and chest, followed by quick friction, is a splendid means of decreasing the likelihood of catching cold or becoming chilled. Older persons may take cold showers or cold plunges in the morning, if it is advisable in individual cases.

To repeat, it is urged that while most acute colds, if not all, are probably due to germs, still acute congestion and more or less nasal secretion may be caused by drafts or currents of cold air causing chilling of some uncovered surface of the body, especially if the person is overheated or is perspiring from exertion or from being in an overheated room. This congestion forms a splendid culture ground for the development of germs.

Children especially should not be subjected to unnecessary infection by being taken into crowded cars, stores or into various assemblages, where it is impracticable to avoid close contact with coughing or sneezing persons who do not properly protect the surrounding atmosphere by using handkerchiefs.

Schoolchildren with acute colds should either be sent home or should be taught to prevent spraying the atmosphere with droplets of infection and thus infecting surrounding children. If a case of acute coryza occurs in a family, the family should understand that it is contagious, and the sick should be isolated from the well as effectively as practicable.

As so many times urged, a child or adult who has repeated colds should be examined and properly treated medically or surgically by a nose and throat specialist. The family should also be taught that the exchange of handkerchiefs and the use of the same towels when one member of the family has a cold or sore throat is inexcusable. Direct contagion by this method is probably very frequent. During all colds the nasal and throat secretions or excretions should be received into paper handkerchiefs, or pieces of cheese-cloth, and either immediately burned or deposited in a paper bag for burning later. If handkerchiefs are used, they should be washed separately and soon.

The harm which a too dry indoor atmosphere can do to mucous membranes of the upper air passages is well described by Wolff Freudenthal.[2] The drying of these mucous membranes caused by evaporation due to the inhaling of too dry air leaves the membranes unprotected, and the first irritant that attacks them may cause an inflammation. It is necessary, therefore, to teach and advise that more moisture be furnished the air of all houses, buildings, schoolrooms, churches, theaters and other places of assemblage.

By all of these methods the frequency and number of nasal colds will be greatly diminished.

Acute coryza having begun, an attempt should be made to abort it. There are various methods of relieving internal congestions, and the general principles are the same in all cases, wherever the localized inflammation may be. These general methods are some means to reduce an increased temperature, some means of bringing the blood to the surface of the body and increase perspiration, some means to produce free catharsis and thus to deplete the blood-vessels and lower the blood-pressure to relieve indirectly the tension in the region of congestion, and some means to prevent the development of the second stage, or stage of secretion, if possible. Methods used to meet one of these indications will many times meet one or more of the others; hence the treatment is often very simple.

If the patient is first seen in the morning, or before the middle of the afternoon, the best treatment is a saline purge of some description, as exemplified by the Seidlitz powder or by the effervescing magnesium citrate or Rochelle salt, or castor oil if that is preferred. If the patient is seen first in the evening, a less quickly acting cathartic is advisable, and none is better than a small dose of calomel, as from 0.05 to 0.20 gm. (about 1 to 3 grains), depending on the age of the individual, combined with 0.50 to 1 gm. (7½ to 15 grains) of sodium bicarbonate. Or, 1 grain of calomel may be given with an ordinary compound aloin pill or tablet. The old-fashioned Dover's powder is still given by many physicians and often works well, but may cause considerable nausea. Also, opium or morphin in any form tends to inhibit free action of the bowels, which is undesirable. One of the best treatments is one of the coal-tar products, such as antipyrin, acetanilid or acetphenetidinum. Any one of these may be given in one fair-sized dose or in two medium-sized doses, or in several small doses. One gm. of antipyrin would be a full dose; 0.50 gm., repeated in five or six hours, would be a medium dose; 0.30 gm. of acetanilid would be a large dose, and 0.10 gm. might be repeated at three-hour intervals for three times. A satisfactory method is a combination of acetanilid with sodium bicarbonate, and a prescription similar to the following is often very valuable:

	Gm.		
℞ Acetanilidi	0|25	or	gr. v
Sodii bicarbonatis..........	2|50		gr. xl

M. et fac chartulas 5.
Sig.: One powder every two or three hours.

A similar combination may be given in tablets, if preferred. It should be remembered that caffein has been shown not to protect the heart from depression caused by large doses of a coal-tar product; therefore, there is no object in adding caffein to such a prescription. When these coal-tar products are ordered, it is well to give coincidently hot lemonade. Perspiration is more readily caused by this means.

Provided the patient is not soon to be subjected to exposure, a hot bath is another efficient means of relieving internal congestions, and can be used coincidently with the other treatment. Acidum acetylsalicylicum (aspirin) is now more largely used than almost any other drug to abort colds. The laity, on account of the instruction which they have received of the dangers of acetanilid and similar drugs, now all buy and use this drug with the greatest freedom. It can cause cardiac depression, and should not be used *ad libitum*. If preferred, it may certainly be ordered.

Rhinitis tablets are sold everywhere to the laity, and are largely used by physicians. These are various combinations of morphin, atropin, strychnin and aconitin. The minute dose of aconitin ordered probably generally has no action. If one desires the activity of aconite, it is best to give it in a tangible form and dosage, namely, the tincture of aconite, a drop perhaps every half hour or hour, until the pulse shows the activity of the drug. However, this treatment ordinarily requires that the patient be seen within a certain number of hours by the physician, to ascertain whether or not the aconite should be stopped, unless the doses are limited in number. The old aconite treatment of colds has mostly given place to the newer treatments described above. The whole rhinitis tablet combination probably represents principally the action of atropin with some help from the morphin, both of which will dry up the secretions of the nostrils and throat. The small amount of strychnin probably is not very active. Sometimes minute doses of quinin enter into these combinations, but that probably is not active. In other words, it is a question if a small dose of atropin sulphate, given frequently, does not act as well as one of these rhinitis combinations.

There is no question about the drying up of secretions by morphin, if this drug is pushed. Rarely is such treatment needed. The old-fashioned treatment of a hot foot-bath, a hot whisky punch, and the patient put to bed is a treatment that is often successful. The upper air passages and the head are relieved from congestion by such treatment, the blood-vessels of the surface are dilated by the alcohol, and the patient perspires more or less and the treatment is conducive to comfort. In this age, however, when other vasodilators are accessible, it is rarely necessary to resort to alcohol.

Quinin sulphate has been used for years as an abortive treatment of colds, and the laity, until more recently adopting acetylsalicylic acid, have always resorted to this drug. Small doses would probably not have any very decided action; large doses are inadvisable at this stage of the congestion because of the tendency to congest the middle ear.

Spraying or snuffing solutions into the nostrils at this stage is inadvisable. The throat may be gargled with warm physiologic saline solution, which is roughly represented by ¼ teaspoonful of salt to half a glass of warm water. If the patient has been known to be exposed to some acute throat or nasal infection, more active antiseptic gargles and sprays may be used; but an acute coryza will rarely be aborted by local treatment.

If the inflammation is not aborted and the second stage develops, that of profuse mucus and some mucopurulent discharge, then cleansing of the nose and throat becomes urgently needed. At this stage all of the foregoing abortive measures should cease. A patient who has been more or less deprived of food, except a small amount of liquid nourishment for from twenty-four to thirty-six hours, may now resume his normal diet.

---

[2] Freudenthal, Wolff: New York Med. Jour., Jan. 3, 1914, p. 1.

The more or less purulent discharge from the nostrils should not be allowed to remain blocking up the passages. Consequently, atomizing with warm saline and alkaline solutions should be more or less frequently done. Various compound solutions or tablets for solution are offered, but there probably is no advantage in these combinations over more simple ones. The simplest cleansing solution is one made from ½ teaspoonful of salt and ½ teaspoonful of sodium bicarbonate to a glass of warm water, or half these amounts for half a glass of water. To be properly soothing, the solution should always be warmed. The same solution may be used as a gargle. If a mild antiseptic is needed, saturated solutions of boric acid or borax are efficient. If stronger antiseptic solutions are required or advisable, hydrogen peroxid is valuable, as 1 part of the official aqua hydrogenii dioxidi to 4 or 5 parts of warm water for a gargle, or 1 part to 7 or 8 parts of warm water for a nasal spray. Nasal spraying and proper cleansing of the nose protects the adjacent sinuses from infection.

Cleansing the nasopharynx by snuffing back a solution from a teaspoon or a small vial, or snuffing back a spray, or gargling and then throwing the head forward and washing the nasopharynx, protects the eustachian tubes from infection. Two cautions should be suggested: first, that douching of the nasal passages should not be done with the nostril blocked, or with a high placed douch reservoir, as the pressure is likely to be sufficient to send fluid into the eustachian tubes or into the sinuses, and cause inflammation of such parts. Most of the patented douch apparatus are inadvisable. The second precaution is that it is not well to cleanse the mucous membrane of the nostrils too thoroughly of mucus before the patient goes into the outside air, especially if that air is dust-laden. The proper time to spray is when the patient is to remain in the house for a short time; or if he is sprayed and then must go out of doors, he may receive a non-irritant oil spray to furnish a coating for the mucous membrane, this to be used after the alkaline spray. Or a small plug of cotton may be placed in the nostrils.

If the secretion from the nose is tenacious and hard to dislodge by blowing the nostrils, ammonium chlorid may be a drug of value. It has been used as a stimulant to the upper air passage mucous membrane as well as to the bronchial mucous membrane. It may be given in a simple preparation as:

		Gm. or c.c.		
℞	Ammonii chloridi..........	5		ʒ iss
	Syrupi acidi citrici.........	25	or	fl.℥ i
	Aquae..............q. s. ad	100		fl.℥ iv

M. et Sig: A teaspoonful, in water, every three hours.

If the coryza tends to become subacute and prolonged, tonic treatment is required; a small dose of quinin and a small dose of iron, with or without arsenic and strychnin, are advisable. Or calcium glycerophosphate may be given in doses of 0.30 gm. (5 grains) in capsule, three times a day, after meals. The following tonic capsule may be used, and the doses may be modified for a child:

		Gm.		
℞	Arseni trioxidi................	0|04		
	Strychninae sulphatis........	0|04		*aa* gr. ⅔
	Ferri reducti..................	1|0	or	gr. xv
	Quininae sulphatis...........	2|0		gr. xxx

M. et fac capsulas siccas 20.
Sig.: A capsule three times a day, after meals.

If the mucous membrane of the nose and throat does not return to health, and the secretion of mucus does not seem to be sufficient, a great promoter of secretion is an iodid, and the best salt is the sodium iodid. The dose required is not large; 0.10 to 0.20 gm. (1½ to 3 grains) three times a day, is generally sufficient.

Various menthol, camphor and pine oil preparations are used as sprays or applications for the nostrils, sometimes with good results, or as inhalants when the nostrils tend to become closed and cause discomfort by occlusion. Such treatment has its use at times. Spraying with suprarenal solutions is sometimes of advantage, but sometimes is followed by more congestion. Some nose and throat specialists use suprarenal preparations constantly. Such treatment certainly many times is efficient in temporarily relieving congestion and giving comfort.

This discussion of the treatment of common colds would not be complete without reference to the vaccine treatment. While the exact value of such treatment has not been determined as an abortive treatment or as a treatment that shortens the course of the disease, the enthusiastic recommendation of such treatment by some writers should be recognized. When there is sinus infection, autogenous vaccines would seem indicated.

An interesting paper on the subject of vaccine treatment of common colds, including considerable bibliography, is that of Dr. Jessie W. Fisher.[3]

ACUTE PHARYNGITIS

The abortive treatment of this inflammation is the same as that described for acute colds; but if a child is discovered to have a sore throat, a swab should be sent to the board of health for examination, and the child should be immediately sent home, lest diphtheria or scarlet fever be the cause of the condition.

With a simple pharyngitis, soothing alkaline gargles, as previously described, should be the treatment. A very simple, pleasant and efficient gargle is as follows:

		Gm. or c.c.		
℞	Acidi borici...............	2		ʒ ss
	Potassii chloratis..........	5	or	ʒ iss
	Aquae menthae piperitae...	200		fl.℥ vii

M. et Sig.: Use undiluted as a gargle, every three hours.

(To be continued)

One Minute Biographs.—No. 1. The Father of Preventive Medicine. The early history of our hero is veiled in myth and mystery. Born of a persecuted race, adopted as a foundling by a princely house, forced to flee the country for committing murder, the subject of this sketch exhibited marvelous insight and remarkable powers of administration and leadership. Although not a physician as we understand the term, and living long before the days of bacteriology, he yet was able to draft and enact a sanitary code whose guiding principles are still regarded as correct. In this code he originated an entirely new system of medicine, totally opposed to the prevailing plan. For the curative and therapeutic methods then universally followed, he substituted the more philosophic and wiser hygienic and preventive method. Moreover, in the regulations which he formulated, emphasis is laid on discharges from the body (blood, pus, mucus) as vehicles of disease, and on personal cleanliness and isolation as the chief means of preventing infection. A hygienist whose influence has made itself felt throughout the world and the father of preventive medicine,—we salute Moses, maker of sanitary laws.—*Weekly Bull. Dept. of Health*, City of New York.

THE CHLORIN CONTENT OF DRINKING WATER

Although chemically pure water does not exist in nature, the substances ordinarily present in solution are not regarded as impurities in the hygienic sense, unless either they are themselves directly injurious to health or from their association are indicative of dangerous pollution although in themselves they may be harmless. Impure water from the hygienic point of view, in contrast with the strict chemical sense, is water that is unfit for domestic use.

The amount of chlorids commonly found in natural waters is not objectionable; in fact, the quantity thus consumed is much less than the amounts constantly used in seasoning food. The quantity of chlorid in potable waters may, however, be an important indication of the pollution of surface waters with sewage, since the latter is rich in chlorid derived from urine. Aside from such accidental contaminations, the chlorin content of waters may vary greatly in different localities owing to natural causes. It is influenced by the proximity to the ocean or other bodies of saline water, by proximity to natural deposits of salt, and by geologic features of the locality. These possibilities must therefore be borne in mind in forming a judgment of the hygienic fitness of potable waters on the basis of their chlorid content.

The health authorities of the state of Massachusetts deserve credit for having demonstrated on a large scale the influence of the proximity of the ocean on the inland ground waters. It had long been appreciated that the amount of chlorin in surface waters near the seaboard is considerably higher than obtains in samples from inland parts remote from the coast. The classic investigations of the Massachusetts authorities about twenty years ago showed very clearly that the contribution of ocean spindrift and blown spray to the surface waters may extend much farther inland than had been suspected. Furthermore, it was demonstrated in Massachusetts and in the adjoining state of Connecticut that the unpolluted surface waters varied in their chlorin figures with surprising uniformity relatively to their distance from the sea. When areas with the same chlorin content were plotted on the map the successively lower "isochlorin" regions were found to run parallel with the coast line, thus demonstrating the influence of the ocean on the inland waters. Within slight margins of error the chlorin of uncontaminated ground waters of a given area approximates a normal, so that the estimation of chlorin would form a rapid method of gaging, for preliminary purposes, the relative purity of any water sample. These facts have made it essential for the sanitary water analyst to know the normal chlorin content of the waters of any given region before passing judgment on the purity of a sample of the water on the basis of the chlorin found in it.

A recent investigation conducted by Barr[1] at the University of Glasgow has confirmed the American finding that the ocean has an influence on the chlorin content of surface waters not limited to the waters of the seaboard only. It is exerted through the blown spray deposited on the land by all forms of precipitation, varying with the distance from the ocean and diminishing as it extends inland. The new report brings out the added fact that the spray particles, following the laws which govern all particulate matter, are more abundant in the lower strata of the air. For this reason the isochlor lines may become deflected by elevations of the land. The influence of the ocean spray is greater where the land is continuously low from the shore, but the prevailing winds also have an unmistakable effect. In the estimation of the ultimate results of the ocean's influence on the chlorin content of inland ground waters, the factors of the configuration of the land surface and wind prevalence are inseparably connected, as the land elevations may in great part assist or nullify any action exerted by the winds. For sanitary science the importance of having certain districts mapped out into areas of known chlorin content in surface waters on which our potable supplies are dependent becomes obvious.

AN OLD-TIME CLINICAL OBSERVER

Popular medical tradition, by one of those curious errors so frequent in popular medicine, makes the "dog-days" the time of the year when dogs are most likely to go mad, to develop rabies. As we have said before,[2] the term "dog-days" refers only to the dog star, which is then in the ascendant and has nothing to do with curs. The disease rabies incidentally spreads more virulently during the cold, damp months of winter than during the summer. The Puget Sound country had its epidemic last year beginning in

---

[1] Barr, W.: The Influence of Ocean Spindrift and Blown Spray on the Chlorine Content of Inland Ground Waters, Jour. Hyg., 1914, xiv, 119.

[2] Rabies and Dog-Days, editorial, The Journal A. M. A., July 18, 1914, p. 246.

December. Hence, if dogs should be muzzled, this should be done in the winter as well as during the summer months. It is at this time too that the evidence of rabies in stray dogs should be sought, to prevent, if possible, the inoculation of human beings.

It is interesting to realize how long ago clinical observers among physicians and surgeons recognized exactly the symptoms displayed by a mad dog, and wrote them down for the benefit of their professional brethren and for the protection of the public. John Ardern, for instance, the old English surgeon of the fourteenth century, who was a specialist on the treatment of fistulas everywhere in the body, gave in one of his lesser works, "On The Classification of Medicines," a description of the symptoms displayed by a mad dog that is nearly if not quite as complete as anything that has been done since. Mr. D'Arcy Power,[3] in his paper on the "Lesser Writings of John Ardern," quoted a paragraph from this which shows the acute powers of clinical observation of the old medieval surgeon. There is a quaintness about the old English in which it is couched that gives it an added interest and proclaims how long ago it was that such fine clinical observation was at work. We should premise that the old word for mad was "wood," and that the old printers used "y" for "i" on every possible occasion.

> The tokenys of a wood dogge ben these; the furste is he knoweth not his lord ne his mayster & he falleth into a voyd goying allone with boowynge of his heed & hangynge of the erys [ears] as other wyse thanne he hadde hem in his he'the & the yene[4] [eyes] of him ben rede & the fome cometh out at the mowth & he wole berke [will bark] at his oune schadowe & he hath ane hos [hoarse] berkynge & other houndes fleene from hyme & berken towardys hyme. And yf a schyvere [slice] of breed [bread] be folden or wette in the bytynge of the sore & yoven [given] a dogge to ete, yf that he ete it, it is a token that the dogge is not wood, for and the dogge be wood that other dogge that the breed is yoven to wole not ete it, but that he be over moche hungry, and yf he denye to ete the seyde breed out-take [except on] the condicione aforseyd thane is the dogge wood.

Ardern dwelt on the length of time that might intervene between the bite and the development of the symptoms, and in this perhaps went farther than most of the pathologists and physicians of our time would care to follow him. There has always been some doubt, however, as to whether even years might not intervene between the bite and its consequences, and whether a person might not be a "carrier" of the as yet unknown microbic cause of rabies and still not suffer from its symptoms, somewhat as do so many pneumonia and diphtheria bacillus carriers. Ardern knew that the first symptom of the development of rabies was hydrophobia, that is, dread of water, because the very thought of swallowing a liquid brought on a spasm of the throat muscles. His paragraph on rabies in human beings deserves to be placed beside his description of the affection in animals.[5]

> The bytynge of a wood dogge is more venemous & perlous [perilous] thane it is of a serpente, ffor the venyme of a wood dogge ys hydd often tymes by the hole yere togydere [whole year together] & other whyle by the ii [two] yere & after some auctours it wole endure vii yere or [ere] it sle [slay] a man. And note wheyther it be longe tyme hydd or schorte or that it slee, there comene tofore to the pacient thes tokenys medlynge & chaungynge of wytte [change of disposition] & resone & abhominacione & lothsomnesse of cold water that is clene & pure. And whane suche sygnys fallen to him that is byten of a wood hound schall unnethe or ellys never [hardly or else never] escape it.

As we learn more of the actual writings of the old medieval physicians and surgeons, we come to realize better that the popular medicine of the middle ages, so full of irrational and superstitious practices, was something quite apart from actually scientific medicine and surgery. The text-books of the old time, so often fortunately preserved for us, show us what worthy colleagues we had in medicine even six and seven centuries ago.

CAN FAT BE ABSORBED FROM THE LOWER BOWEL?

Under the ordinary conditions that prevail in the alimentary tract, 95 per cent. of all the fat ingested has disappeared from it before the intestinal contents reach the lower end of the ileum. There is experimental evidence to show that absorption of fat is not interfered with by extirpation of the large intestine. The lower end of the bowel clearly is not necessary for a satisfactory utilization of the fats of the diet.

From the evidence just cited, it does not follow, on the one hand, that the large intestine cannot participate in the absorption of fats if occasion arises, nor does it give the slightest assurance, on the other hand, that fats can find their way directly from this portion of the gastro-intestinal canal into the nutrient mediums of the body. The clinical practice, still somewhat in vogue, of injecting fat emulsions in the form of nutrient enemas into the rectum naturally presupposes an absorptive capacity on the part of the lower bowel. All of the modern studies of fat absorption, in turn, postulate a digestive cleavage of this foodstuff before it can traverse the walls of the alimentary tract.

Several years ago Neumann found that the occurrence of suspended fat particles in greater or lesser abundance in the blood can be demonstrated by an ultramicroscopic examination, and the comparative richness of the circulating medium in fat thus estimated. This method of examination has accordingly been applied in the physiologic institute of the University of Vienna to settle the mooted question of fat absorption after rectal administration.[1] Nakashima found that the characteristic picture presented by the blood under the ultramicroscope—the sign of fat absorption after milk or cream are taken by mouth—is completely missed after rectal introduction of the same fat-yielding foods. Occasionally after introduction of emulsified fats in larger quantities into the lower bowel, signs of slight absorption of them were noticed; not, however, if the return of the contents beyond the ileocecal valve and toward the mouth was prevented by ligation of the intestine at that point. Histologic examination of the intestine has likewise borne out the evidence furnished by the other method. After undue distention of the large intestine there may be some travel of contents backward toward the regions where adequate digestion and absorption of fat is known to occur. It is futile, however, to depend on this uncertain and rather abnormal phenomenon of antiperistaltic propulsion for effective nutritive results. These facts serve to emphasize anew the shortcomings of the older attempts at rectal feeding, to the defects of which we have directed attention on previous occasions.[2]

[3] Power, D'Arcy: The Lesser Writings of John Ardern, Section on History of Medicine, Seventeenth Internat. Med. Cong., London, 1913.

[4] The old spelling "yene" is less common than "eyne," but it was the typesetters who regulated spelling in the early days of printing. They spelled as they pronounced. Consistency in spelling was not then the jewel we have made it.

[5] Power, D'Arcy: Tr. Seventeenth Internat. Med. Cong., Section on History of Medicine, London, 1913.

In contrast with the failure of fat emulsions to be transported into the tissue fluids through the wall of the lower bowel is the fact of their disappearance from the peritoneal cavity. Like other fine suspended particles, those of fat can be withdrawn from this abdominal space and make their way via the lymphatics into the peritoneal circulation. The transport is far more easy from the peritoneal than from the somewhat similar pleural cavity. Any pathologic change, such as inflammation in the membranes lining these tissue spaces, at once stops the absorptive processes.

THE BOOKKEEPING OF HUMANITY

In the study of disease, whether for the development of measures of prevention or for cure, uniform and accurate vital and morbidity statistics are so essential that no apology need be made for repeatedly referring to the subject. It is to be deplored, however, that even after many years of agitation, only about 60 per cent. of our population is included within the approved area of registration of births and deaths. Satisfactory figures regarding morbidity are recorded in a very much smaller area. The American Medical Association has continually and consistently fought for such measures. In 1846, by resolution, the Association requested the profession to take immediate concerted action to secure legislation to establish offices for the collection of vital statistics, and provided for a committee from each state to report on a uniform system of registration of marriages, births and deaths. In 1855 a resolution was adopted providing for a committee in each state and territory to study and "report on its medical topography, epidemic diseases, and the most successful treatment thereof." Some action looking to these ends has been taken at various sessions since that time, and has culminated in the model bill for the registration of births and deaths, drafted and indorsed by the Association in cooperation with other national bureaus and bodies.

Trask,[1] in a recent article, gives a brief historical account of the efforts in this and other countries to secure adequate registration laws, the requirements of effective laws, the methods of computation of vital and morbidity statistics, the results and conclusions to be obtained from them and the practical benefits to be derived from their study concerning the distribution of diseases, their prevalence, epidemiology and the means for their eradication. At present, twenty-four states have satisfactory registration of births and deaths. As shown by Trask, only one disease — smallpox — is reportable in all the states; such a highly infectious disease as scarlet fever in 45; diphtheria in 46; measles in 31; tuberculosis in all forms in 29; typhoid fever in 35; whooping-cough in 27, and cerebrospinal meningitis in 29, while many other dangerous diseases are reportable in a smaller number of states, dwindling down in many instances to one or two. Ophthalmia neonatorum, a disease responsible for much blindness and disability, is reportable in only fourteen states, and the occupational diseases, which are coming to be recognized as the source of a large proportion of the burden of expense of public hospitals and other public and charitable institutions, are so far reportable in only fourteen states, and this number only for one of the most easily recognized and prevalent occupational diseases — lead poisoning.

Needless to state, the value to the public of accurate vital and morbidity statistics, collected and recorded under a uniform system in all the states, would be great. Opposition by physicians to measures for this purpose is indefensible. Their responsibility in this respect is stated in an emphatic way by Trask when he says:

> Among practicing physicians, at least in the United States, there has at times been the feeling that the knowledge of a disease in a patient is privileged information which they should not be called on to impart. In communities where the law requires the notification of the disease this feeling has no legal basis and the physician who does not make report is not a law-abiding citizen. But aside from the legal aspects of the matter there would seem to be little justification for such a course. Every physician has a number of individuals or families who look to him, and properly so, not only for treatment, but also for such reasonable protection from dis-

[1] Trask, J. W.: Vital Statistics, a Discussion of What They Are and Their Uses in Public Health Administration, 1914, Supplement 12, Pub. Health Rep.

> case as he is able to give. The failure to report the occurrence of a case of communicable disease in one patient may lead to its spread to others among his clientele whose rights he has ignored. He therefore violates the intent and spirit of the ethical principle of the protection of patients, among whom must be considered the well together with the sick. The notification of disease is in the interests and for the protection of the community, and as his patients are usually members of the community their interests are ignored and because of the antisocial whim or supposed convenience of the individual affected with a notifiable disease, they are deprived of the protection they have a right to expect. It would seem that the physician who fails to report his cases of preventable diseases required to be notified may properly be considered as actively obstructing public health administration.

Victor C. Vaughan[2] thus states the obligation of the physician to the public:

> In the future the training of the medical man must be developed largely with a view to his broader relations to the public. His proper function must be to prevent, rather than cure disease. The physician's duties are to become more and more largely official in the sense that his services are to be rendered to the community, and not exclusively to the individual.

The collection of information concerning the communicable diseases, the bookkeeping of humanity, is as important, if not more so, than any type of census which a nation may make, and adequate, uniform vital statistics laws constitute the first step in securing them.

SEASONAL VARIATION IN COMPOSITION OF THYROID GLAND

If special proof were needed of the importance of an accurate standardization of therapeutic products prepared from natural resources without the refinement and chemical purification which applies to most of the inorganic compounds and alkaloids, for example, it would be found in the evidence furnished by recent studies of the very marked seasonal variation in the iodin content of the thyroid gland of different species of animals. We have already called attention to the work of Seidell and Fenger[3] on this subject. These investigators have had exceptional opportunities to obtain suitable animal material for their studies, and have used products from the very places which serve as sources for the preparation of gland products in this country. Their findings in respect to the existence of seasonal variations have been verified in a general way by data obtained in England from sheep.[4]

A repetition of the analyses of the iodin content of the thyroids of sheep, beef and hog extended for another year by the American investigators have substantiated their earlier statements and included additional determinations to show that other constituents than iodin vary regularly with the season. Thus there is a change in the phosphorus and ash content of these glands, and the amounts of these constituents vary inversely with the iodin. This is explained on the assumption that phosphorus does not form a part of the active iodin complex of the gland, but only of the supporting glandular tissues. An increase in the percentage of iodin would, therefore, naturally be accompanied by a decrease of phosphorus. Consequently it appears that neither the composition of the active iodin complex nor that of the supporting tissues of the gland changes with the season, but only the relative amounts of the two.

Several factors may be considered of importance in accounting for the seasonal change in composition and activity of the thyroid gland. Thus atmospheric temperature, diet and periods of activity of the reproductive functions might play a part. A consideration of the several causes of the seasonal change has led the public health authorities to the conclusion that the environmental temperature factor is the most important of all. Physiologically it is, of course, interesting to learn the true reason for these functional variations; but from the point of view of the therapeutic use of thyroid products, on the other hand, it is important to realize the necessity of standardizing for administration substances present in raw materials of varying potency.

Current Comment

HEALTH IN OUR ARMY

The Report of the Surgeon-General of the Army for 1914 is a document of unusual interest. The outline of the report in the letter of transmissal states that the non-effective rate for disease for 1913 (the calendar year covered by the report) is 23.97 a thousand, the lowest rate ever recorded for our army. This rate indicates the average number of men in every thousand incapacitated for duty each day during the year. The death rate for disease was 2.57, the total number of deaths being 397, 40 of which were from tuberculosis, 23 from pneumonia, 17 from nephritis and 15 from organic heart disease. Probably the most interesting portion of the report is that dealing with the control of preventable diseases. The record made in our army in the obliteration of typhoid fever has become a subject of world-wide comment among military and sanitary authorities. Only three cases of typhoid fever occurred in the army during 1913; two were in recently enlisted recruits who were admitted to the hospital with the disease inside of the first six days of service, while in the third case, only partial immunity through vaccination had been established. All three of these patients recovered. By way of contrast, the report states that in 1912, there were 18 cases with 3 deaths; in 1911, 44 cases with 6 deaths; in 1910, 142 cases and 10 deaths, and in 1909, 173 cases with 16 deaths. Among all the troops scattered along the Mexican border and in large camps in Texas, not a single case of typhoid has occurred in an inoculated man since June 4, 1912. This means that typhoid fever as a military disease, as an accompaniment of military service and camp life, is practically a thing of the past. Only those familiar with the awful ravages of this disease in all previous wars under all conditions in which large numbers of men were herded together under unfavorable conditions can appreciate the enormous economic and military value of this fact. The report is full of interesting data, so numerous as to make it possible to refer only to the most interesting. The medical department of the army, June 30, 1914, consisted of 426 medical officers, 91 reserve officers, 16 contract surgeons, 28 commission dental surgeons, and 39 contract dental surgeons. The remainder of the 5,044 persons connected with the department were army nurses and members of the hospital corps. Of the 19 candidates who had passed the preliminary examination for appointment to the medical corps, 17 successfully completed the course of instruction in the army medical school and 16 were recommended for commissions. The library of the Surgeon-General's office contained on June 30, 1914, 219,494 volumes and 330,320 pamphlets on medical and surgical subjects. The army medical museum contains 47,120 specimens. Reports from the various hospitals, laboratories, territories and provinces are all of great interest and impress the reader with the wide range and scientific thoroughness of the work done by our army medical corps.

PRACTICAL PHARMACOLOGY

The simplification of our materia medica, as represented in the lists of remedies in New and Nonofficial Remedies and in Useful Drugs, has made possible the adoption of rational therapeutic measures by those who are convinced of the inefficiency of methods heretofore in vogue. The brief descriptions in these works do very well for those who are already familiar with the actions of the drugs listed, but are not sufficient for a completely intelligent and discriminating use of such drugs. This knowledge the practitioner is assumed to have obtained in courses of pharmacology in the medical school. However, pharmacology has made such great strides that the teachings of fifteen years ago would be rather unreliable to-day as regards many subjects. Moreover, the subject is so full of details, that attendance on a single course of lectures results usually only in general impressions and not in a real working knowledge. The general practitioner is often accused of ignorance of pharmacology, but in general we believe that such ignorance is due to sheer inability to keep up with the advances in general medical knowledge. There is reason to believe that need of this knowledge is widely felt and is becoming ever more acute as the profession is getting away from the old-time ready-made prescriptions. Whether these were proprietary or merely "Favorite Formulas" they did not demand an intimate knowledge of drug actions. Where there were so many shots in the blunderbuss, it seemed rather immaterial to know just where they would hit. However, with the progress of medicine, it has become pretty clear that the disease was rarely hit by such scattering shots, whatever else they might destroy. The profession is quite well convinced of the failure of the various "compounds," and is ready to try a more direct marksmanship. Before it can do this successfully it must have a more accurate knowledge of its weapons, the drugs. It is true again that this knowledge may be obtained from the various text-books on pharmacology. However, none of these is written precisely for the practitioner who is contemplating turning over a new leaf. Again, many men, with the very best intentions, find it difficult to read a text-book from cover to cover, but would follow with interest a serial presentation of the subject. It is in response to this demand that The Journal is presenting in serial form[1] an outline of the facts of modern pharmacology prepared especially for the practitioner, giving the important elementary facts which the doctor needs to understand regarding the use of drugs; written from the standpoint of its special audience; not assuming too much familiarity with modern discoveries in the allied sciences, but counting on a more practical knowledge of disease than is customary in the ordinary text-books which are intended primarily for students.

THE ADVERTISING POLICY OF THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES

The *American Journal of the Medical Sciences* is, with one exception, the oldest medical journal in the United States. For nearly ninety years it has recorded the progress made in medicine, not only in this country, but also abroad. Few journals in the United States have for so long held such a high place in the regard of the best men in our profession. No journal has presented in its reading pages material of a higher grade of scientific excellence. In this respect it has been a star of the first magnitude in the medical literature in America. With one exception it has always stood for the highest ideals in medicine. This exception has been its advertising pages. While these have not at any time been of such character as to deserve serious condemnation, at the same time they have been used to promote preparations that were not creditable to American medicine. This, undoubtedly, was due largely to a theory, not only in medical but also in lay journalism, that there is a separation of the literary pages from the advertising section that absolves the editor from all responsibility for the latter. Now even this exception is removed; for, while no regular announcement has been made in the journal itself, we understand that hereafter no advertisements of proprietary medicines will be admitted to its pages that have not the approval of the editor. The publishers of the *American Journal of the Medical Sciences* are to be congratulated on the advanced stand they have taken; it means much to scientific medicine to have this journal aid in the efforts that are being made for more rational therapeutics in this country.

CORONER REFORM IN NEW YORK

June 13, 1914, at the request of the New York City Club, Mayor John P. Mitchell ordered an investigation of the coroners' office of that city. The report[1] has just been made public. As was expected by many, the management and methods of the coroners' offices were found to be open to grave criticism, while the entire system of elective coroners is shown clearly to be expensive and inefficient. The report states that the elective coroner in New York City represents a combination of power, obscurity and irresponsibility which has resulted in inefficiency and malfeasance, that under the present system, the honest and efficient performance of the important public duties entrusted to the coroner are practically impossible. Of the sixty-five coroners in New York City since consolidation, not one, according to the report, was qualified for the position, most of the candidates being selected "to balance the ticket and for purely political reasons," many of them being absurdly ignorant of the scientific and legal aspects of their work. Most of the coroners' physicians have also been appointed for political reasons, "have been drawn from the ranks of medical mediocrity," and their medical examinations and official reports are without scientific or legal value. Lack of supervision has favored graft and extortion. "Far from being of assistance," says the investigator, "the death certificates of coroners' physicians introduced a large degree of error into the vital statistics of the city." An analysis of 800 inquisition papers shows in 40 per cent. complete lack of evidence to justify the certified cause of death. Incompetent medical work of the coroners' physicians deprives the community of an absolutely necessary deterrent to crime. Numerous homicides have failed of detection for this reason. Infanticide, poisoning and criminal abortion, according to the report, can be carried on almost with impunity. The system of coroners' juries makes the administration of justice in the Coroners' Court a scandal and farce. They can be and are easily packed, they offer a ready means of petty extortion, and their verdicts are of no legal value. The records of the coroners' office are meager, uninforming and practically valueless. Coroners have compelled the employment of favorite undertakers, have injured the rights of deceased workmen, and have helped corporations to escape from liability for workmen's deaths. The report also states that the coroners' office is overmanned with unnecessary employees at salaries grossly in excess of the value of their services. The present coroners' system costs the city of New York over $172,000 a year It is distinctly branded by the report as a public scandal and disgrace which should be abolished immediately. A system of medical examination, similar to the plan now in operation in Massachusetts, is proposed. Skilled and experienced pathologists appointed by the mayor as the result of competitive examination will, it is estimated, save the city at least $50,000 a year, will terminate the present ignorant inefficiency and corrupt performance of the elective coroners' functions, and for the first time in the history of New York City will utilize the facts of legal medicine for the protection of the community. The scathing statement of facts in the report, as shown by the summary above, places before the New York General Assembly the definite responsibility for present conditions and future improvement. The historic office of coroner has long since ceased to be of value for performing its original functions and has never, with occasional exceptions, been developed to its full possibilities. The adoption of this reform in New York should be an example to all of our other large cities to investigate the work of the coroners' office in their own city and to institute immediate measures for better methods. It is true that conditions in all large cities are not as bad as in New York, but this is due to the accidental fact that a competent man has been elected coroner, rather than to any merit in the system.

HARPER'S WEEKLY ENTERS THE LISTS

Many of our readers will remember the exposé by George Creel of the C. H. Carson fraud operated from Kansas City, Missouri. Carson was a quack who fleeced his victims by selling them tissue paper supposed to be "magnetized" and by dispensing "vital force" in the form of petrolatum containing red pepper. In the January 2 issue of *Harper's Weekly*, Mr. Creel commenced a series that bids fair to arouse wide interest. The first article was a general introduction to the subject. In the present issue of *Harper's* (January 9) Mr. Creel gets down to specific cases. Under the head of "Suffering Women" he takes up such nostrums as Wine of Cardui, Viavi, and Chichester Pills, the Cora B. Miller mail-order concern, the Fort Wayne fakeries —now fortunately out of existence—and Harriet M. Richards or the Woman's Mutual Benefit Company. Altogether times seem to be looking dark for the exploiter of proprietary frauds. Movements like these instituted by high class publications such as *Harper's Weekly* do much to indicate a change in public opinion on the subject of fraudulent proprietary remedies.

The Requisites of the Modern Doctor.—To achieve the greatest success in his practice, the modern doctor must be a man possessed of logical mind, medical skill and moral courage. He must not only be able to recognize the early signs and symptoms of diseased conditions, and to draw correct conclusions therefrom, but must also have the courage to tell his patients of his findings truthfully and fearlessly. . . . On the other hand the doctor of to-day owes a duty to the state. . . . By reporting promptly all cases of communicable disease that come under his notice, the doctor lends a valuable service not only to the community but also to his individual family. A man who allows cases of diphtheria to go without treatment until they are moribund, who refuses or fails to recognize tuberculosis until the lungs are filled with râles and the sputum with tubercle bacilli, or who neglects cases of cancer until they are inoperable, or at least beyond recovery from operation, has no place in the modern practice of medicine. The people are demanding better things and they are entitled to more consideration; on the other hand men who are prepared to practice modern medicine need have no fear that there is no demand for such service.—Guy L. Kiefer, *Journal Michigan State Medical Society*, October, 1914.

Medical News

(Physicians will confer a favor by sending for this department items of news of more or less general interest; such as relate to society activities, new hospitals, education, public health, etc.)

ILLINOIS

Sanatorium Site Purchased.—The city commissioner of Rock Island has purchased a site for a municipal tuberculosis sanatorium at Seventeenth Street and Brashar. The site consists of 4.33 acres for which $4,500 was paid. The medical commission, in charge of the plan for the proposed institution, consists of Drs. Joseph De Silva, Louis Ostrom, Jr., and Bernard J. Lachner.

Chicago

Work of the Iroquois Hospital.—During the last year 17,437 emergency cases were cared for at the Iroquois Emergency Memorial Hospital, nearly 7,000 more than in the previous year.——At the eleventh annual services of the Iroquois Memorial Association, held December 30, Health Commissioner George B. Young, Dr. Patrick Machler and Dr. Clara P. Seippel were the principal speakers.

Psycopathic Hospital Report.—Dr. Haim I. Davis reports that during 1914, 2,807 patients were received at the hospital of whom 1,677 were men and 1,130 women. The patients were distributed as follows: Chicago State Hospital, Dunning, 1,177; Elgin State Hospital, 397; Kankakee State Hospital, 516; Watertown State Hospital, 7; Peoria State Hospital, Bartonville, 29; Jacksonville State Hospital, 1; discharged cured, 633; transferred to County Hospital, 2; died, 36.

Hospital Staff Selected.—President Reinberg of the Board of County Commissioners of Cook County has nominated the following staff of consulting physicians and the nominations have been approved by the county board: Drs. Arthur D. Bevan, Frank Billings, Charles P. Caldwell, James A. Clark, Alfred C. Cotton, Arthur R. Edwards, William A. Evans, Edward A. Fischkin, Burton Haseltine, James B. Herrick, Albrecht Heym, Anton A. H. Holmboe, Charles E. Kahlke, Jacob S. Kauffman, Blue Island, Franklin H. Martin, Mary G. McEwen, John B. Murphy, Albert J. Ochsner, John R. Pennington, Stephen R. Pietrowicz, William E. Quine, John A. Robison, Otto L. Schmidt, Daniel A. K. Steele, Daniel P. Teter, Camillo Volini, Charles J. Whalen and George B. Young.

INDIANA

Medical Dispensary at Muncie.—A free medical dispensary at Muncie was opened December 19.

Personal.—Drs. William N. Wishard, John F. Barnhill and John H. Oliver have resigned from the staff of the Indianapolis City Hospital.——Dr. Francis M. Magers, Churubusco, is under treatment at St. Joseph's Hospital, Fort Wayne.

MASSACHUSETTS

State Health Council Sworn In.—The oath of office was administered December 12, to the State Advisory Health Council.

Hospital Site Purchased.—The State Board of Insanity has purchased a site containing 281½ acres north of Trapelo Road, Waltham, for $68,500, on which to establish the new Metropolitan Insane Hospital.

Medical Lectures.—In accordance with its usual custom the Faculty of Harvard Medical University is giving its course of free medical lectures at Harvard Medical School on Sunday afternoons, from January 3 to May 9.

Personal.—Dr. Frederick C. Brigham, Springfield, was stabbed in the abdomen by an unknown assailant, December 25, and is said to be in a critical condition.——Dr. Sylvester E. Ryan, Springfield, has been appointed associate medical examiner of Hampden County, vice Dr. Theodore S. Baco, Springfield, resigned.——Dr. William J. Delehanty, Worcester, has been appointed a member of the board of trustees of the Worcester State Hospital, succeeding Dr. Samuel B. Woodward, resigned.——Dr. Francis W. Anthony, Haverhill, has been elected president of the Massachusetts Society of Examining Physicians and Surgeons.——Dr. Frederick L. Bogan, Boston, has been elected a member of the school committee.——Major Robert W. Forster, Lawrence, has resigned from the medical corps of the National Guard.

NEVADA

Hygienic Laboratory Announcement.—The State Hygienic Laboratory of the University of Nevada at Reno, announces its readiness to perform the complement fixation test for syphilis on Thursday of each week. The test is offered to the people of the state through their physicians free of charge. Specimens received at the laboratory later than Thursday noon will not be examined until the following Thursday.——The laboratory offers bacteriologic and biochemical examinations and analyses for the diagnosis of communicable diseases, and also assistance in the prevention and control of communicable diseases within the state.

NEW YORK

Personal.—Dr. John H. Cotter has resigned as a member of the Poughkeepsie Board of Health.——Dr. William C. Wood, president of the Gloversville Board of Health for ten years, has resigned.

Health Movies.—The motion pictures prepared by the State Health Department for the Panama Pacific Exposition were exhibited December 16 in Albany, and will be shown throughout the state before they are taken to California. The first series illustrates Infant Welfare and the second the Evils of Insanitary Surroundings.

New York City

New Morgue Opened.—The new morgue in connection with Bellevue, which is in the basement of the Pathological Building at First Avenue and Twenty-Ninth Street, was opened recently, and 150 bodies were removed from the old morgue. The new morgue is to be known as the mortuary and has greatly improved arrangements for the identification of bodies.

Personal.—Dr. Arnold Sturmdorf has been elected president of the New York Physicians' Association for the coming year.——Dr. A. H. Page of Kings County Children's Hospital, Brooklyn, was operated on for appendicitis, December 25, and is reported to be doing well.——Drs. Mabel Palliser of Brooklyn and Edith Bertine have been appointed interns to Bellevue Hospital. There are now five women on the staff at Bellevue.

Quadricentenary of the Birth of Vesalius.—A meeting in commemoration of the four hundredth birthday anniversary of Vesalius was held at the New York Academy of Medicine, January 7, at which Dr. William H. Welch, Baltimore, delivered an address on "Vesalius and the Spirit of the Time"; Dr. Fielding H. Garrison, editor of the *Index Medicus,* spoke on "Anatomical Illustration Before and After Vesalius," and Dr. Harvey Cushing of Harvard Medical School delivered a lecture on "The Portraits of Vesalius," illustrated by lantern slides. In connection with this meeting there was a public exhibition of early editions of the works and plates of Vesalius and of the anatomists and surgeons of his time. This exhibition was open from January 5 to 9, inclusive.

Patent Medicines Controlled by Sanitary Code.—At its meeting, December 31, the Board of Health adopted a completely revised sanitary code, which has twenty-three new sections. The most important of these regulates the sale of patent medicines and requires that the names of every ingredient used in preparations of this class shall be registered with the Department of Health. This regulation goes into effect on Dec. 31, 1915. This ordinance was passed in the face of very strong opposition on the part of interested parties, and its passage was largely due to the strenuous efforts of Dr. Sigismund S. Goldwater. This article further states that any proprietary medicine shall be deemed misbranded if it does not contain all the ingredients as filed with the Health Department, or if it contains more than the ingredients as filed. Other sections of the code require that coroners must notify the Health Department of the death of any person immediately after they receive such information; that in the manufacturing, handling and sorting of cigars and cigarettes no person engaged in such work shall at any time touch with lips, teeth or tongue any cigar, cigarette or tobacco to be offered for sale; that no person with tuberculosis or other contagious disease can be employed as a teacher in a public or private school without permission from the Health Department, nor shall such persons be permitted to manufacture or alter garments in tenements unless the article is for the use of the person making it, nor shall such a person be permitted to work where food and drink are prepared or sold, and all workers in such places shall be prepared to submit to a physical examination by the department. A number of other minor changes have been made in the code which will greatly add to efficiency of the public health administration.

NORTH CAROLINA

Commercial Travelers' Room Opened.—A new room in the Presbyterian Hospital, Charlotte, furnished and outfitted by the Travelers' Protective Association and the United Commercial Travelers, has been opened and is now ready for use. It is known as "The Drummer."

Personal.—Dr. James A. Anderson, McAdenville, has removed to Charlotte.——Dr. Francis J. Clemenger, Asheville, has returned after two years' laboratory work in England.——Dr. W. R. Brandon, after eighteen months' hospital service in Baltimore, has located at Midway.——Dr. Benjamin E. Washburn, Rocky Mount, has resigned as health officer of Nash County to accept a position with the Rockefeller Foundation.

Instruction of Health Officers.—The State Board of Health proposes to conduct in the executive offices and the various other working departments, including actual work in the field with some of the best of the whole-time county health officers, a school, or course of instruction covering a period of some six to seven months for the instruction of physicians proposing to become county or municipal health officers in the state. The tentative course as outlined by the secretary of the board, Dr. Watson S. Rankin, Raleigh, is as follows: Four weeks in the executive offices where fundamentals as well as details will be studied; four weeks in vital statistics, followed by three weeks in a study of popular sanitary instruction; four weeks at the State Tuberculosis Sanatorium; four weeks in the Hygienic Laboratory, concluding with six weeks of actual work under a field worker in county health work. At the close of the period of instruction, if the work has been performed satisfactorily, a certificate signed by the governor of the state and the officials of the board will be awarded. In this way it is hoped to be able to offer counties and municipalities medical men who at once will be able to engage in active practical public health work without having to find out many things by experience. This will also tend to standardize the county and municipal health work throughout the state.

PENNSYLVANIA

Quarantine Lifted.—The State Live Stock and Sanitation Board on December 30 issued a notice of modification for the foot-and-mouth quarantine, relieving Philadelphia and Juniata counties from all restrictions and reducing the area in all of the other counties under quarantine except Berks, Lehigh, York, Lancaster and Lebanon. Pittsburgh and the townships near it are retained in quarantine. The ban on hunting because of the danger of spreading the disease was raised.

Not a Passenger Killed on the Pennsylvania System.—Not a passenger out of 188,411,876 carried on all the lines of the Pennsylvania Railroad system last year was killed. The Pennsylvania Railroad lines east of Pittsburgh in the past two years carried 311,675,794 passengers and not one of them was killed in an accident to a train. In four of the past seven years, 1908, 1910, 1913 and 1914, more than 558,000,000 passengers—five times the population of this country—were carried by the Pennsylvania lines east of Pittsburgh without a single one being killed in a train accident.

Personal.—Dr. Henson F. Tomb, Johnstown, who was operated on at the Memorial Hospital in that city recently, is reported to be improving.——Dr. Jerry C. Murphy, York-Haven, is reported to be seriously ill with pneumonia at his home.——Dr. Gregg A. Dillinger, Pittsburgh, who was stabbed by an unknown assailant at the door of his home December 18, is improving, but is not out of danger.——A banquet was given at the University Club, Pittsburgh, December 19, by the active staff of the West Penn Hospital in honor of Dr. James W. Macfarlane, who after thirty-seven years of service on the active staff of the hospital, has retired and been made a member of the consulting staff. Dr. Macfarlane was presented with a silver loving-cup.——Dr. Harry W. Bernhardy, Rochester, was given a birthday surprise party by the physicians of Beaver Valley, at which he was presented with a gold watch chain.

Philadelphia

Appropriation for Unemployed.—On December 10 Councils, with only one dissenting vote, made an appropriation of $50,000 for the relief of the unemployed of the city. This appropriation is to be expended by the departments of health and charities from the Emergency Aid Committee.

To Raise Funds for Woman's College.—At a recent meeting of the alumnae of the Woman's Medical College of Pennsylvania and others interested in the institution, an organization was effected for the purpose of planning ways and means for raising money for the college. The meeting was called by the graduate council December 13.

Personal.—Dr. Charles W. Burr has been appointed consulting neurologist and Dr. P. B. McCullough consulting dentist at the Municipal Hospital.——Dr. James William White has just published a pamphlet entitled "A Primer of the War for Americans," in which he discusses the cause of the war from the pro-allies' point of view.

Presbyterian Hospital to Replace Present Buildings.—To provide for the future needs of the Presbyterian Hospital, the board of trustees of that institution has decided to replace the present structures at Thirty-Ninth and Filbert Streets with a new group of buildings in the Georgian style of architecture. It is proposed to build seven structures, the cost of which will exceed $1,000,000. The plans are in charge of the building committee, which has chosen John T. Windrim architect to prepare plans.

Fund for Paris War Hospital.—At the meeting of the committee on the Philadelphia Ward in the American Ambulance Hospital, held December 15, in the Franklin Building, Dr. James William White, chairman of the committee, reported that the fund had reached the sum of $7,024.98. An executive committee was appointed, consisting of John Wanamaker III, Charlton Yarnall, Dr. George E. de Schweinitz, William Ellis Scull, Dr. Robert G. LeConte, Dr. James William White, Effingham B. Morris and John J. Collier.

Hospitals Need Money.—Many Philadelphia hospitals will have to curtail the extent of their work unless they soon get money in the shape of private contributions. These institutions are caught between the increase of charity patients and an increase in the cost of supplies due to unemployment, and to a decrease in contributions due to the financial depression and the plea for charity in unusual cases. The Episcopal Hospital, long considered one of the strongest institutions in the city, has been forced to cut down its limit of ward patients from a flexible point somewhere above 400 to a maximum of 275. The number of patients, however, who come to the hospital for day treatment has not been limited.——Other hospitals which may have to cut down the number of ward patients are the Pennsylvania, the Woman's College Hospital, Samaritan, St. Christopher's and St. Timothy's.

SOUTH CAROLINA

New Hospital for Negroes at Columbia.—On December 1 a hospital for negroes was opened at Columbia by Dr. Matilda A. Evans of that city.

Donation for Indigent Baptists.—The Baptist State Convention, at a recent meeting, agreed to donate $6,000 during the year for the care of indigent patients in the Baptist State Hospital, Columbia.

Appeal for Pellagra Hospital.—Dr. James L. Jefferies, representing the Spartanburg County Society and the Spartanburg Health League, appeared before the county grand jury, November 28, to prevent an appeal for an increased appropriation for the maintenance of the pellagra hospital at the county home, from $4,000 to $6,000.

Health Day in Schools.—Greenville County has designated Friday, December 11, as a day for the study of public health in the schools. The day is to be devoted to cleaning and making sanitary the schools and their surroundings, reading compositions by the children on public health topics and talks by physicians on public and personal hygiene.

State Society Meeting.—The Medical Society of South Carolina celebrated its one hundred and twenty-fifth annual meeting, December 14, at Charleston and the following officers were elected: president, Dr. Edward F. Parker; vice-president, Dr. Robert Wilson, Jr.; secretary, Dr. Albert Nathan, and treasurer, Dr. Daniel L. Maguire, all of Charleston.

SOUTH DAKOTA

Personal.—Dr. Harry C. Durkee, Gettysburg, has been appointed physician to the Cherry Creek Indians, with headquarters at Faith.——Dr. Andreas A. Wipf, Freeman, is reported to be under treatment in a hospital in Yankton, as the result of an automobile accident near Yankton.

State Board Advocates Preventive Service.—The report of the State Board of Health asks for better financial provisions for its work in the state and states its conviction that its efforts will be more effective if devoted to preventive rather than curative measures in its attempt to control contagious, communicable and occupational diseases. The board also advocates that the state supply diphtheria antitoxin at the cost of production.

TENNESSEE

Personal.—Dr. William E. Martin, Columbia, suffered a loss of $10,000 by fire, December 10.——Dr. John A. Price, Nashville, has been appointed physician to the state penitentiary, vice Dr. Z. D. Massey, Sevierville, resigned.

Middle Tennessee Physicians Hold Meeting.—At a meeting of the Middle Tennessee Medical Association held at Murfreesboro, November 19 and 20, the following officers were elected: president, Dr. Oval N. Bryan, Nashville; vice-president, Dr. Frank B. Reagor, Shelbyville, and secretary-treasurer, Dr. Roy W. Billington. Lebanon was selected as the next place of meeting.

Work of the Rockefeller Sanitary Commission in Tennessee to be Continued Temporarily by the International Health Commission.—With the passing out of existence of the Rockefeller Sanitary Commission on Jan. 1, 1915, the Tennessee State Board of Health has faced the necessity of discontinuing the hookworm campaign initiated by the commission. The hookworm campaign has made a deep impression and aroused great public interest. Surveys have been conducted in over sixty counties, and dispensaries have been operated in forty-four of these. There are a number of counties, however, in which dispensaries should be operated. The International Health Commission has therefore agreed to carry on the work of the Rockefeller Sanitary Commission temporarily in the state. It is expected that this will permit continuance of the work to July 1, 1915, by which time it is hoped that means will be found for its further continuance as necessary.

TEXAS

City Hospital Opened.—The Municipal Hospital, Austin, was opened to receive patients January 1.

North Texas Physicians Hold Meeting.—The North Texas Medical Association held its seventieth semi-annual session at Dallas, December 8 to 10, and elected the following officers: president, Dr. Raleigh W. Baird, Dallas; vice-president, Dr. Murphy M. Morrison, Denison; secretary, Dr. Hugh Leslie Moore, Dallas; treasurer, Dr. Charles R. Johnson, Gainesville.

Abolition of Quarantine Officers.—The State Board of Health at its final meeting, December 9, recommended the abolition of quarantine officers along the Rio Grande border and their employment as state inspectors and also recommended that the salary of the state health officer be increased from $2,500 to $4,000 a year and that he be required to devote his entire time to the duties of his office.

Personal.—Dr. Carrie Weaver Smith, Dallas, has been appointed a member of the committee to arrange the sociologic exhibit at the Panama-Pacific Exposition, and has gone to New York for conference with the national committee.——Dr. John B. Thomas, Midland, sustained a loss by fire of $3,500 December 19.——Dr. William M. Brumby, San Antonio, has succeeded the late Dr. John M. McCutchan, Waco, as assistant medical director of the Amicable Life Insurance Company.——Fire at Granbury, December 18, caused a loss of $600 to Dr. A. R. Jarrett.——Dr. Luther F. Johnson has been appointed full-time medical inspector for the city schools of Beaumont.

VIRGINIA

Personal.—Dr. John Mann, Richmond, has started for Europe, where he will work in the Russian Red Cross.——Dr. Edward A. Gorman has been elected health officer of Alexandria to succeed himself.——Dr. W. B. Ashburn, South Norfolk, who has been ill with septicemia for four months, is convalescent and has resumed practice.

Honor Deposed Hospital Head.—Physicians of Richmond and their wives were the hosts at a banquet given at the Arlington Hotel, December 18, in honor of Miss Marsh, superintendent of the Reid Memorial Hospital, and her assistant, Miss Sands, who were recently deposed, notwithstanding the protests of the majority of physicians of the city.

CANADA

Begins Sanitary Bulletin.—The Quebec Municipal Board of Hygiene and Statistics has commenced the publication of a sanitary bulletin. It will be issued monthly and will contain articles in English and French.

Hospital News.—The new St. Justine Hospital for Children has been formally opened in Montreal. It contains 180 beds.——The Children's Hospital, Toronto, has been enlarged by the addition of a new wing providing accommodation for fifty-two more patients.

Medical Reciprocity.—The Ontario Medical Council, at its meeting December 2, expressed its approval of the principles of reciprocity between Ontario and Great Britain. The matter was finally referred by the countil to a subcommittee, which was directed to bring in a report at the next meeting after ascertaining what the British Medical Association is ready to offer.

Free Medical Care for Toronto Citizens.—At a meeting of the Toronto Board of Health, December 16, and on suggestion of Dr. Charles J. C. O. Hastings, Toronto, medical officer of health, it was decided to furnish free medical advice to citizens who cannot afford to call in a physician, and the medical officer of health was authorized to employ a physician to attend to these cases.

Personal.—Dr. Cecil S. Mahood, medical officer of health, Calgary, Alberta, has been elected a Fellow of the Royal Institute of Public Health, London, England.——Dr. Arthur E. Ross, M.P.P., Kingston, is in charge of No. 1 Field Ambulance at Salisbury Plain, England. He has with him six recent graduates of Queen's Medical Faculty and three medical students of the fourth year. There are also three other Queen's graduates in the medical service and one in the navy.——Lieut.-Col. Herbert S. Birkett, M.D., dean of the medical faculty of McGill University, Montreal, is to be in command of the general hospital offered by McGill University for service in France. The personnel will consist of twenty-one officers, who must be members of the medical faculty of McGill, 100 men in the rank and file who will be drawn from the medical student body of all years. Prof. John George Adami and Dr. John M. Elder may go with this unit.——Dr. Arthur Mignault, Montreal, has been raised to the rank of lieutenant colonel in the army medical corps.——Dr. James McGregor, who for some time practiced in Megantic, Quebec, but who has recently been connected with the Presbyterian Hospital, New York, has been appointed surgeon with the European contingent on the American ambulance staff.——Dr. Charles J. Edgar, North Hatley, Quebec, has been appointed a surgeon in the military hospital at Netley, England.——Dr. George C. Hale, London, has been commissioned as medical officer of the Eighteenth Battalion for overseas service with the Second Contingent, and has been assigned to duty as medical officer at Queen's Park encampment, succeeding Major Archibald V. Becher, London, appointed sanitary officer of the camp.——Dr. James Samson, Windsor, announces that he will soon retire from practice and will engage in consultation work in Detroit.

GENERAL

Tri-State Society Meeting.—The Northern Tri-State Medical Association of Indiana, Ohio and Michigan announces that it will hold its forty-first semi-annual meeting in Elkhart, Ind., January 12.

New Officers.—At the annual meeting of the Porto Rican Medical Association held at San Juan, the following officers were elected: president, Dr. Pedro Gutiérrez Igaravidez, San Juan; vice-president, Dr. M. de la Pila Iglesias, Ponce; secretary, Dr. José S. Belaval, San Juan; and treasurer, Dr. Jacinto Avilés, San Juan.

Western Surgeons Hold Meeting.—The twenty-fourth annual meeting of the Western Surgical Association was held in Denver, December 18 and 19, under the presidency of Dr. Byron B. Davis, Omaha, Neb.; and the following officers were elected: president, Dr. Joseph Rilus Eastman, Indianapolis; vice-president, Dr. Van Buren Knott, Sioux City, Ia.; and secretary, Dr. Arthur T. Mann, Minneapolis (reelected). The 1915 meeting will be held in Des Moines, Ia.

A Warning.—The Journal is informed that a man, purporting to represent the Keystone Mfg. Co., Pittsburgh, appeared in Lima, Ohio, and sold to physicians such apparatus as hypodermic syringes, stethoscopes, thermometers, etc. He made collections in advance, allowing an extra percentage for cash with the order. Several physicians were victimized, as no goods were ever shipped and letters sent to the firm were returned unclaimed. Physicians should be wary of all offers of this character.

Southern Surgeons and Gynecologists Meet.—The twenty-seventh annual session of the Southern Surgical and Gynecological Association was held at Asheville, N. C., December 15 to 17, under the presidency of Dr. John Wesley Long, Greensboro, N. C. Cincinnati was selected as the next place of meeting and the following officers were elected: president, Dr. Bacon Saunders, Fort Worth, Texas; vice-presidents, Drs. Thomas S. Cullen, Baltimore, and Samuel M. D. Clark, New Orleans; secretary, Dr. William D. Haggard, Nashville, and treasurer, Dr. Le Grand Guerry, Columbia, S. C.

Hospital Ship for Fishing Fleet.—The U. S. Revenue Cutter *Androscoggin*, which has been transferred into a hospital ship for fishermen, has arrived at Baltimore ready for service. She will take on fuel and supplies sufficient for a two months' cruise, and will make a stop at Gloucester, Mass., where her commander will confer with the owners of the fishing fleet. From Gloucester the *Androscoggin* will cruise around Brown's Bank and the south shore of Nova Scotia, and will be prepared to receive for treatment fishermen incapacitated from illness or injury. Late in February the *Androscoggin* will return to Boston and outfit for a second cruise to Banquereau and Sable Island banks.

Bequests and Donations.—The following bequests and donations have recently been announced:

Home for Aged and Infirm Hebrews, New York, $1,000, and the residuary estate valued at about $30,000, to be divided among charitable institutions, principally the Home for the Blind, by the will of Esther Wyman.

Visiting Nurse's Association of Chicago, $5,000; Children's Memorial Hospital, $2,500 after a lapse of ten years, by the will of George H. Hale, Chicago.

Chester County, Pa., Hospital, $71,376.85 by the will of Townsend S. Lamborn of West Bradford Township, Chester County.

Montefiore Home, New York City, $2,500, by the will of Albert Rich.

Subscription for the hospital Saturday and Sunday Association, $17,935, up to January 1.

Examination for Physicians for Indian Service.—The United State Civil Service Commission announces an open competitive examination for physicians, men only, to be held on February 3, at various places throughout the United States, to fill a vacancy in the Indian service at the Haywood School, Wisconsin, carrying a salary of $1,100 a year. Unmarried eligibles without dependents are desired; applicants must be graduates or senior students in recognized medical schools, between 21 and 40 years of age, and citizens of the United States. Those who desire to take this examination should apply for Form 1412 stating the title of the examination for which the form is desired, to the United States Civil Service Commission, Washington, D. C., or the Secretary of the United States Civil Service Board, at any of the places at which the examination will be held.

Biologists Meet in St. Louis.—The American Association of Anatomists and the Federation of American Societies for Experimental Biology, comprising the American Physiological Society, the American Society of Biological Chemists, the American Society for Pharmacology and Experimental Therapeutics and the American Society for Experimental Pathology, held their annual meetings in St. Louis December 28-30 as the guests of the Washington University Medical School. The scientific program contained about 180 titles. Addresses were delivered in memory of Drs. S. Weir Mitchell and Charles S. Minot. On Wednesday afternoon an excursion of the city was made in automobiles. Stops long enough to permit of tours of inspection were made at the Washington University and at the affiliated hospitals, the Barnes and St. Louis Children's. About 200 visitors were in attendance. Perhaps the most important business transacted during the session was in relation to the business conduct of the *American Journal of Physiology*. This journal, which since 1898, has been edited by Dr. William T. Porter, becomes by virtue of action taken at this meeting the official organ of the American Physiological Society, by which it is owned and managed. The management of the journal is now vested in the council of the society, which has been so reorganized as to insure for the journal the stability of policy that is essential to its successful publication.

FOREIGN

Switzerland Quarantines Against Cholera.—The *Policlinico* states that Switzerland has officially declared a quarantine against Russia, Austria, Servia and Galicia on account of the prevalence of cholera in these countries.

Spanish Academy of Medicine Elects a Senator.—It is one of the privileges of the Spanish Academia de Medicina that it is entitled to a seat in the senate. The member of the academy recently elected senator in this way is Dr. B. G. Alvarez, one of the editors of the *Pediatria Español*, the official organ of the Sociedad de Pediatria de Madrid.

Another International Prize Postponed on Account of the War.—The Umberto I prize offered by the Istituto Rizzoli will not be awarded this year and the date limit for sending in articles in competition has been postponed to Dec. 31, 1915, instead of 1914. This prize of $700 is awarded by the Provincial Council of Bologna for the best work or invention in the line of orthopedics.

Sanitary Brigade Organized at Madrid.—The first flying sanitary brigade in Spain has just been organized at Madrid and the occasion was celebrated by a *té de honor* in the Palace Hotel tendered by the Bloque Sanitario Español to the governor, all the alcaldes, public health officers and other officials of the province of Madrid. The brigade is intended to bring to bear at once all the measures known to science to aid the local public health authorities in case of an epidemic or catastrophe of any kind at any point in the province. The autotrucks of the brigade are equipped with sterilizing plants, services for vaccination, serotherapy, etc. Dr. Call, medical inspector for the province, is in charge.

WAR NOTES

Aid for Blinded Soldiers.—An endowment fund to aid soldiers who have lost their eyesight from wounds in the war has been started by Frau Minden, who has given the Berlin city authorities 100,000 marks ($25,000) for the purpose.

Cholera in Austria.—The *Wiener klinische Wochenschrift* reports 844 cases of cholera with 331 deaths in Austria during the week ended November 7; including 90 cases in Vienna with 10 deaths. During the following week there were 78 cases in Vienna with 19 deaths.

Olympic Games Building as Hospital.—It is stated in a British medical journal that twenty-five emergency hospitals have been established in Berlin, with accommodations for 20,000 men. One of the larger hospitals is housed in the new buildings erected for use in connection with the Olympic games.

Red Cross Festschrift.—In honor of its silver jubilee, the German Red Cross has issued a stately volume, profusely illustrated, containing the reports and experiences of the physicians who have been at the head of the various expeditions sent out by the Red Cross during the latest campaigns. J. Springer, Berlin, is the publisher and the price is to be 40 or 42.50 marks (about $10 or $10.50).

Automobile Ambulance Corps.—The Australian Expeditionary Force, which has gone to join the allies in Europe, is accompanied by an ambulance corps equipped with a special field ambulance, provided with all apparatus and appliances necessary for all kinds of military surgery, including a Roentgen-ray apparatus. The sides of the car are so constructed as to carry tentage sufficient for a field hospital.

Personal.—Major William J. Crookston, Pittsburgh, M.C., N.G., Pa., assigned Fourteenth Infantry, has accepted a directorship in the Austrian Red Cross and has started for Washington en route to Budapest.——It is announced that Drs. James William White, John B. Deaver and Charles H. Frazier and six other surgeons of Philadelphia will soon sail for Europe to take charge of a ward, endowed by Philadelphians, in the American Ambulance Hospital, Paris.——Dr. Alexis Carrel, New York, [illegible] nsive tour of investigation to the French [illegible] at the front.

Aid for Belgian Profession.—The report of the treasurer, Dr. F. F. Simpson, Pittsburgh, of the committee of American physicians for the relief of the Belgian profession, for the week ended Jan. 2, 1915, lists the following contributions:

H. F. W.	$ 25.00
B. C.	2.50
D. W. C.	25.00
V. P. G.	25.00
Mrs. J. B. M.	100.00
E. F. B.	5.00
C. W. N.	25.00
In memory H. N. C.	10.00
S. J. M.	15.00
D. B.	25.00
Total	$257.50
Disbursements	None
Contributions previously reported	$405.00
Grand total	$662.50

Our French Exchanges.—A communication has been received from the publishers of the *Revue de Médecine* and the *Revue de Chirurgie* stating that the departure for the seat of war of the editorial staff of these journals and of the printers from the publishing house made it necessary to suspend publication of both. They announce, however, that as soon as the war is over they will resume publication of the twin *Revues* and that the missing numbers for 1914 will be made up. The journals will be resumed under the same conditions as heretofore and the publishers express confidence that the subscribers and friends of the journals will keep up their interest in them which has made possible their success and the leading position they occupy in the world of science. Both are monthlies and were founded about thirty-four years ago. The contents of each have been listed and reviewed regularly in the Foreign Current Literature Department of The Journal.

Red Cross Notes.—The 200 boxes of clothing and blankets for the Belgians, recently sent to Holland, have been received and distributed.——An additional shipment of hospital supplies for the use of the Red Cross units at Pau, France, has just been made. This shipment includes 200 pounds of chloroform, 1,000 pounds of bandages, 5,000 yards of gauze, 10 bales of absorbent cotton, 200 pounds of permanganate of potash, tetanus antitoxin, surgical instruments and other hospital equipments.——Among the chief needs in the war zone are clothing for women and children and babies, overcoats for men, pajamas, shirts, convalescent robes, socks and bed linen.——During the past week a supplementary shipment of 100 cases of miscellaneous hospital supplies was sent to the British Red Cross, London.——The American Red Cross now has 44 surgeons and 150 nurses on duty in the war zone.——In response to an appeal, the American Red Cross, on December 31, sent a donation of $3,000 to an American committee in Pekin and made arrangements with the Surgeon-General of the Army to purchase supplies on the Pacific Coast for immediate shipment to the Pekin committee.——On December 31 the American Red Cross forwarded through the State Department $31,000 for the British, French, German and Servian Red Cross societies. Of the $6,000 sent to Great Britain, $3,000 is to be used to build two cottages, adjoining the Addington Park Hospital, Canterbury, for enteric fever cases.

LONDON LETTER

London, Dec. 18, 1914.

The War

THE TREATMENT OF WOUNDS

The controversy on the antiseptic versus the aseptic treatment of wounds of the war continues. Sir Anthony Bowlby, consulting surgeon to the expeditionary force, has contributed an important paper on the subject to the *Lancet*. He points out that in this war there is never an armistice for the burial of the dead or the relief of the wounded, and it is usually only at night that stretcher bearers can remove men who cannot walk. On the other hand, the motor ambulances cannot take the wounded to the clearing hospitals by night because they would draw fire if they showed lights. Men who are shot in attacks lie outside the lines unaided even for days, for stretcher bearers would be shot if once they went toward the lines to help either British or Germans. Men are left lying in the wet mud of manured fields till their torn trousers and their wounds are so soaked in a mixture of blood and dirt that it is impossible even to get the torn muscles mechanically clean, let alone aseptic. The rifle bullets are different from those used in the Boer War and produce more severe wounds; another cause of difference is that wounds are often produced at very short distances. When the opponents are only a few yards apart the most typical explosive effects are produced. Bowlby has seen the greater part of the muscles of the forearm torn and extruded through a huge rent in the skin. But the most horrible wounds of all are produced by shells. The limb is often so violently contused by the mass of jagged metal tearing its way through all obstruction that far beyond the wound the tissues are so injured that they slough in large masses. Large portions of clothing covered with mud are frequently thrust deep among the torn muscles.

Treatment at the clearing stations, for which any available building such as a barn or railway waiting room, town hall, or church is used, is attended with great difficulty. The wounded are brought here on the stretchers from the field. Perhaps the station is equipped for 200, and in less than twenty-four hours 1,000 wounded have to be dressed. It is seldom possible to remove all the blood and mud stained uniforms because there is little to take its place, and in fractures of the lower extremities the dressings and splints have to be applied as the patient lies in the stretcher raised on trestles. The usual routine for all flesh wounds of the punctured variety and for all abdominal and thoracic wounds is to paint the skin far around with 2 per cent. iodin in alcohol and to wash the wound with either phenol (carbolic acid) from 1 : 20 to 1 : 40; iodin from 1 to 2 drains to the pint; or strong hydrogen peroxid. The dressings consist of mercuric cyanid and absorbent wool. For a fracture without extensive laceration or comminution the same procedure is adopted; but for an extensive fracture with laceration, whenever it is possible, the wounds are enlarged under anesthesia and washed out with antiseptics.

THE BELGIAN PHYSICIANS' AND PHARMACISTS' FUND

In spite of the demands on the medical profession from all sorts of funds established since the war and the serious financial losses resulting, a generous response is being made to the request to help Belgian confrères in their grievous plight. A scheme is being organized to obtain the help of the whole of the medical and pharmaceutic professions. The British Medical Association, the various medical corporations and the universities, are cooperating. Already about $10,000 has been received. Many physicians are offering the hospitality of their homes to Belgian confrères, and the medical societies and universities are freely thrown open to them. At a meeting of the Royal Society of Medicine the chairman, Sir Henry Morris, welcomed a number of Belgian physicians and expressed the high appreciation of the profession for their heroic nation and the deep sympathy they all felt for the terrible sufferings they had borne. A Belgian physician, Dr. Phillippe, returned thanks for the generosity of the society in cordially receiving them and placing its wonderful library and laboratories at their disposal. At a meeting of the Edinburgh Obstetrical Society, Professor Jacobs of Brussels gave an address on the position of the medical profession in Belgium. He was most cordially received at a reception to welcome him given by the president. Their country had suffered terribly and physicians had not been spared. They were devoting their care, and if necessary, their lives to their country. But they had no medical stores, their homes and pharmacies were ruined, and some were carrying on practice in ruined buildings.

THE DUTY OF MEDICAL STUDENTS

Sir Donald Macalister, president of the General Medical Council, stated in his official address that the need for efficient physicians and surgeons in the field and at home is not less urgent than the need for efficient soldiers and sailors. He felt it his duty to press this consideration on senior students who, though they have nearly completed their curriculum, are ready to forego the prospect of early qualification and to enroll themselves straightway in the combatant forces. He has received a letter from Surgeon-General Sir Alfred Keogh which contains the following passage: "I think with you that the senior student is best fulfilling his duty to the country by getting his degree and then joining the army. The need for young qualified men will become great, and I should regret that the supply should be diminished."

THE MANUFACTURE OF ANILIN DYES

In a previous letter to The Journal I have mentioned the project, supported by the government, of manufacturing in this country the anilin dyes for which we have been almost entirely dependent on Germany. Fortunately this country is not wholly unprepared. Since 1878 there has existed in Leeds a School of Tinctorial Chemistry and Dyeing, which during the past years has been doing a work which will now make it possible to establish the manufacture of dyestuffs in this country, on such a basis as will enable it, even after the termination of the war, to maintain its position in the face of foreign competition. At the head is Prof. A. G. Green, an eminent man in the chemical world. The University of Leeds—of which this school forms an important technologic department—in response to an appeal from the government placed its resources at the disposal of the Chemical Trades' Committee, of which Lord Moulton is the chairman. Professor Green has temporarily relinquished his ordinary duties in order to give his whole time to the service of this committee. The staff of his department, together with a number of chemists appointed for the purpose by the government, are devoting their energies to the elucidation of the many difficult and complex problems involved in the work.

PARIS LETTER

PARIS, Dec. 10, 1914.

The War

SECONDARY HEMORRHAGES IN MILITARY WOUNDS

These constitute one of the most trying problems in military surgery. A wound may appear to be almost cured when suddenly fifteen or twenty days after the injury, sometimes even later, a secondary hemorrhage occurs and often is fatal. Even in some cases in which the hemorrhage is controlled for the time, it occurs again without apparent cause and the patient dies. These secondary hemorrhages were the subject of an interesting discussion at the Société de chirurgie.

The first question is that of determining whether these hemorrhages, which appear to be extensive, are not in reality to be attributed to an unrecognized arterial wound. This is the opinion of Professors Quénu and Pierre Delbet, and the greater number of surgeons who took part in the discussion. Dr. P. Reynier thinks that secondary hemorrhages probably result from the late detachment of a little cicatrix of the arterial wall which has been grazed by the bullet. On the other hand, Dr. P. Sebileau has often observed in military wounds vascular effusions at a distance.

For the treatment of these hemorrhages, it is not sufficient to apply compression or to make injections of gelatinized serum. It is necessary to cleanse the wound energetically, to curet the granulations and after being assured that the arterial trunk is injured, to tie the ligature as nearly as possible at the level of the hemorrhagic focus. Notwithstanding, as Dr. Quénu remarked, it is necessary to bear in mind the difficulties caused by the inflammation on the vascular walls. If necessary, the ligation should be made in healthy tissue leaving the operator free to perform the operation that follows. Dr. Tuffier thinks that it is necessary to distinguish different cases: (1) when the wound is not very septic and the artery is easily accessible, the two ends of the wound should be ligated; (2) if the wound is septic and gangrenous, the ligature should be tied as near as possible but outside of the septic focus in healthy tissue; (3) if the wound, while sufficiently aseptic to permit a ligature in situ, is situated where it is impossible to tie the ligature, the artery must be sought above the wound and in an easily accessible region; (4) when the bleeding vessels cannot be reached, a deep incision should be made, the focus cleansed and tamponed and then horse-serum injected.

There are cases in which the most careful search discovers no arterial lesion. Pierre Delbet advises curetting the wounds in such cases and removing all the granulating tissue, for it is this which bleeds. During this curetting of the granulations, which are extraordinarily abundant and thick, the hemorrhage is profuse, but it stops as soon as tissues which are apparently almost normal are reached. To this curetting it is advisable to add a dressing with sodium nucleinate.

Dr. Quénu recently observed a case of secondary hemorrhage due to a wound of the external iliac vein. The ulceration of the vessel seemed in this case to be attributable to the pressure of the drain introduced into the wound, although this drain had constantly diminished in volume. Dr. Savariaud remarked that the ulceration of iliac vessels in contact with the drains is nothing exceptional when these drains are of rigid rubber, cut transversely by the scissors at the moment when they are used. Such accidents may easily be avoided by the use of molded drains.

FITNESS FOR ACTIVE SERVICE BY MEN AFFECTED WITH AORTIC INSUFFICIENCY

At one of the last sessions of the Société médicale des hôpitaux de Paris, Dr. C. Aubertin declared that out of a comparatively small number of patients he had been able to observe, five, aged from 20 to 30 years, who, though affected with aortic insufficiency, had passed without accidents through a campaign including the battle of the Marne. None of them had shown edema, arhythmia, crises of angina, stethoscopic signs at the side of the lungs, increased volume of the liver or the slightest asystolia.

A SOCIETY FOR FACILITATING COMMUNICATION BETWEEN THE WOUNDED AND THEIR FAMILIES

There has just been formed at Paris, under the title of the Oeuvre de la visite aux blessés, an association for the purpose of bringing to wounded soldiers now being cared for in provincial hospitals, whose families live in the departments of the Seine and Seine-et-Oise and cannot go often to see them, any articles (letters, clothing, etc.) that these families may wish to send.

Death of Dr. Barde

Dr. Auguste Barde has recently died at Geneva, aged 74. He studied at Berlin under Dr. Albert von Graefe and at Paris under Dr. Meyer. At one time Dr. Barde attended Baron Adolphe de Rothschild at Naples when the latter was the victim of an accident to his eye. As a token of gratitude, the baron founded at Geneva a very well-organized ophthalmologic hospital of which Dr. Barde was director for more than a half century.

BERLIN LETTER

BERLIN, Dec. 1, 1914.

The War

CHOLERA IN PRISON CAMP

In the Russian prisoners' camp at Ulm, eleven cases resembling cholera have been detected, to which four patients have already succumbed. Although the diagnosis at this writing has not been established, appropriate measures have already been taken to hinder the spread of an epidemic. In East Prussia, also, a soldier has been brought back who was infected with small-pox in Galicia. This patient, also, is strictly isolated. With reference to the fact that we are likely to get typhus fever from Russia, which otherwise is almost entirely unknown to us, the government has issued a circular in which advice to physicians for combating the disease and especially directions for disinfection are contained.

MENTAL DISTURBANCES IN WAR

The Berlin clinician, Professor Bonhöffer, recently delivered a very interesting address on the experiences so far encountered with reference to mental disturbances in the war. He opposed the widely spread public opinion that, on account of the mental and physical demands which the war brings with it, mentally sound men become insane. Still, severe emotional strain is not without effect on the mental condition of the population, sometimes acting with great intensity. One may compare the frame of mind of the population through the mobilization with the extravagant ideas which appear in any individual who misinterprets so many things. Thus, a spy was brought to the Charité who in full daylight had climbed a wall in order to look at the barracks yard. He proved to be one of the imbeciles well known in the Charité. Another remarkable general phenomenon was the confusion of facts in the memory. Such positive and negative falsifications of memory show themselves also in the reports from foreign countries. All these disturbances are an acute lack of harmony between the intellect and the emotional side of the mind. In the army itself such a disturbance of mental equilibrium may be observed. Bonhöffer could report on seventy soldiers and officers who had been brought to the nerve clinic of the Charité since the mobilization. More than half of them showed a psychopathic constitution; 16 per cent. showed alcoholism in addition to epilepsy, symptomatic psychoses and organic diseases of the brain. Chronic alcoholism with delirium was observed only among the reservists and Landwehr men during the mobilization, induced by the excitement and the hardships of the journey and the prohibition of alcohol on the road. A striking feature is the large number of psychopaths who were thrown out of mental equilibrium either on account of apprehension or a slight wound or the exertions of the war. In times of peace the management of the army lays the greatest stress on excluding these elements from the army. If, in spite of this, the war permits the appearance of such psychopaths in the army, the explanation is in the continued emotional strain, the lack of sleep, etc., which finally bring about a condition in which pathologic phenomena disclose the slight and hitherto latent disposition. Among patients so affected there were only five active soldiers. There is no psychosis peculiar to war. That which was described as such in the Russo-Japanese War must be designated as a neurasthenic psychosis. Hysteria gives a good prognosis in contrast with traumatic neuroses involving financial interests. Bonhöffer has so far had no experience on which to base an opinion as to whether an increase of mental disease in the army is to be expected from the war. In the English army in the latter part of the campaign against the Boers, such an increase was observed, and also in the Russo-Japanese War. After the war of 1870 there occurred an increase of mental diseases both in the civil population and in the military.

Marriages

Roland R. Cross, M.D., U. S. I. S., Pine Ridge, N. Dak., to Miss Isabel Hunter of Dahlgren, Ill., at Rushville, Neb., November 19.

Charles D. Frederick O'Hern, M.D., Tulsa, Okla., to Miss Frances Hazel Larkin of Bartlesville, Okla., in November.

James George Williamson, Jr., M.D., Columbia, Tenn., to Miss Margaret Frierson of Chattanooga, Tenn., December 9.

P. A. Surg. Hugh de Valin, U. S. P. H. S., Washington, D. C., to Miss Frances Watson of New Orleans, December 28.

Wirt Bradley Dakin, M.D., Los Angeles, to Miss Hariette Ruecker of Portage, Wis., at Pasadena, Cal., December 31.

William Francis Finley, M.D., Lonsdale, Minn., to Miss Mary Grace Donovan of McGregor, Ia., September 15.

Harry Denton Stryker, M.D., Reading, Pa., to Miss Minnie W. Gring of West Reading, Pa., December 18.

Samuel Bernard Rosenzweig, M.D., to Miss Josephine Frances Taub, both of New York City, December 2.

William Aaron Bessesen, M.D., Albert Lea, Minn., to Miss Beatrice Gjertsen of Minneapolis, January 4.

Carroll Edward Foley, M.D., Lovettsville, Va., to Miss Charlotte Woody of Richmond, December 12.

Percy Hoxie Wood, M.D., to Miss Amelia Alcorn Russell, both of Memphis, Tenn., November 25.

Hugh Warren Brent, M.D., to Miss Helene R. Vogeler, both of Baltimore, December 16.

Foy Roberson, M.D., to Miss Helen Gribble, both of Durham, N. C., December 10.

Walter Edgar Barbour, M.D., to Miss Leake Clarke, both of Atlanta, Ga., recently.

Deaths

Paul Fitzsimons Eve, M.D. University of Tennessee, Nashville, 1878; College of Physicians and Surgeons in the City of New York, 1880; a Fellow of the American Medical Association; formerly president of the Tennessee State Medical Association and Nashville Academy of Medicine; local surgeon at Nashville for the Louisville and Nashville, and Nashville, Chattanooga and St. Louis railways and the Nashville Railway and Light Company; surgeon to Eve's Infirmary; one of the most prominent surgeons of the South; died at his home in Nashville, December 26, from septicemia, aged 58.

Robert Walker Ramsey, M.D. Jefferson Medical College, 1874; a Fellow of the American Medical Association; from 1900 to 1906 a member of the Pennsylvania State Board of Medical Examiners; coroner of Franklin County, Pa., from 1879 to 1882; a member of the medical staff of the Chambersburg Hospital and vice-president and director of the Chambersburg Trust Company; died at his home in Chambersburg, December 26, from arthritis deformans, aged 54.

John Wesley Carhart, M.D. College of Physicians and Surgeons, Chicago, 1883; a member of the State Medical Association of Texas; and for three years county physician of Lampasas County; for many years a clergyman of the Methodist Episcopal Church; who claimed to have built the first automobile of the present-day type; died at his home in San Antonio, Tex., December 28, from heart disease, aged 80.

Morley Da Costa Bates, M.D. Rush Medical College, 1891; a Fellow of the American Medical Association; instructor in medicine in his Alma Mater; a member of the staff and treasurer of Grace Hospital, Chicago, and physician to the Metropolitan West Side Elevated Railway Company; died in the Presbyterian Hospital, Chicago, December 24, from cerebral hemorrhage, aged 42.

Robert Dandridge Jackson, M.D. Medical College of the State of South Carolina, 1851; a member and one of the organizers of the South Carolina Medical Association; a surgeon in the Confederate service throughout the Civil War; for many years a practitioner of Jefferson County, Ala., died at the home of his daughter in Orrville, Ala., December 20, aged 84.

Roscoe McClellan Huffman, M.D. Toledo (Ohio) Medical College, 1913; a member of the staff of the Pool Hospital, Port Clinton, Ohio; while driving across the tracks of the Lake Shore Road at Port Clinton, in his automobile, December 20, was struck by a train and instantly killed, aged 25.

Franklin Van Buren Gildersleeve, M.D. New York University, New York City, 1866; a hospital steward and later assistant surgeon of U. S. Volunteers during the Civil War; afterward a practitioner of New York City; died in St. Francis' Hospital in that city, December 26, aged 72.

Andrew Jackson Smith, M.D. College of Physicians and Surgeons in the City of New York, 1863; a member of the Connecticut State Medical Society and for many years a practitioner of East Bridgeport, Conn.; died at his home, December 20, aged 75.

Kathrine Jane Rayl, M.D. University of Michigan, Ann Arbor, 1902; a Fellow of the American Medical Association; president of the Galion (Ohio) Hospital Association; died at the home of her mother in Galion, December 19, aged 51.

George G. Hitchcock, M.D. New York Homeopathic Medical College, 1870; for more than forty years a practitioner of South Hadley Falls; died at his home in that town, December 20, from the effects of a fall two days before, aged 65.

Wallace Kirkwood Hughes, M.D. Western Reserve University, Cleveland, 1859; for nearly half a century a practitioner of Berlin Center, Ohio; died at his home in that place, December 19, from arteriosclerosis, aged 79.

Francis Alvin Tillinghast, M.D. University of Vermont, Burlington, 1867; one of the best known practitioners of the Pawtuxet Valley, R. I.; died at his home in Arctic Centre, R. I., December 24, from pneumonia, aged 71.

Edwin Brown Harper, M.D. Ohio Medical University, London, 1896; for four years a member of the Ohio State Legislature from Summit County; died at his home in Clinton, December 2, from tuberculosis, aged 48.

Richard J. Leonard, M.D. University of Louisville, Ky., 1880; medical director of the Fraternal Bankers of America and Royal Fraternal Union; died at his home in St. Louis, December 19, from pneumonia, aged 64.

Emory Sherman, M.D. Rush Medical College, 1885; of State Center, Ia.; for many years a practitioner of Independence and Alden, Ia.; died at the home of his daughter in State Center, December 3, aged 78.

Calvin Jacob Paleir, M.D. Vanderbilt University, Nashville, Tenn., 1894; of Blowing Rock, N. C., and president of the local bank; died at the Charlotte (N. C.) Sanatorium, December 16, from arteriosclerosis.

James S. Eves, M.D. University of Pennsylvania, Philadelphia, 1862; a Fellow of the American Medical Association; died at his home near New London, Pa., December 17, from cerebral hemorrhage, aged 66.

Jay Sylvester Corcoran, M.D. University of Michigan, Ann Arbor, 1883; of Ubly, Mich.; a Fellow of the American Medical Association; died in the Hubbard Hospital, Bad Axe, Mich., December 10, aged 60.

John F. A. Clausnitzer, M.D. University of Leipzig, Germany, 1878; for more than thirty years a practitioner of the East Side, New York City; died at his home, December 20, from nephritis, aged 61.

James T. Strohecker, M.D. Jefferson Medical College, 1879; for many years a practitioner and druggist of Beavertown, Pa.; died at his home in that place, December 15, from heart disease, aged 62.

Edward Russell Cogswell, M.D. Harvard Medical School, 1867; a member of the Massachusetts Medical Society; died at his home in Cambridge, Mass., December 22, from pneumonia, aged 73.

Robert B. Travis, M.D. Memphis (Tenn.) Medical College, 1858; for more than half a century a practitioner of Benton County, Tenn.; died at his home in Camden, December 19, aged 84.

James E. Talbott, M.D. Medical College of Ohio, Cincinnati, 1875; a member of the Indiana State Medical Association; died at his home in Linton, Ind., December 18, aged 66.

Frederick Milton Phillips, M.D. New York University, New York City, 1893; of Newburgh, N. Y.; died from heart disease, December 21, while making a professional call, aged 45.

Abner White, M.D. College of Physicians and Surgeons, Keokuk, Ia., 1880; for fifty-two years a practitioner; died at his home in Missouri Valley, Ia., December 12, aged 89.

Isaac N. Leyda, M.D. University of Pennsylvania, Philadelphia, 1876; until 1907, a practitioner of Manor, Pa.; died at his home in Sulphur, Okla., December 10, aged 69.

The Propaganda for Reform

In This Department Appear Reports of the Council on Pharmacy and Chemistry and of the Association Laboratory, Together with Other Matter Tending to Aid Intelligent Prescribing and to Oppose Medical Fraud on the Public and on the Profession

NEUROSINE, DIOVIBURNIA, GERMILETUM AND PALPEBRINE

Report of the Council on Pharmacy and Chemistry

Neurosine, Dioviburnia, Germiletum and Palpebrine are "shotgun" proprietaries typical of the polypharmacy of the past three or four decades. They are marketed by the Dios Chemical Company, St. Louis, Mo. On the recommendation of the referee, the Council has authorized the publication of this report.

W. A. Puckner, Secretary.

Neurosine

According to the manufacturers, each fluidounce of Neurosine represents:

"Bromid of potassium, C. P.	40 grains
"Bromid of sodium, C. P.	40 grains
"Bromid of ammonium, C. P.	40 grains
"Bromid of zinc	1 grain
"Extract Lupulin	32 grains
"Cascara sagrada, fl. ex.	40 minims
"Extract Henbane	.075 grain
"Extract Belladonna	.075 grain
"Extract Cannabis indica	.60 grain
"Oil Bitter Almonds	.060 grain
"Aromatic Elixirs."	

No physician would think for a moment of prescribing all of the drugs contained in Neurosine for any one condition. Yet physicians are urged to use this nostrum in insomnia, hysteria, neurasthenia, migraine, neuralgia, delirium tremens and in a host of other conditions.

It is recommended in the treatment of epilepsy on this ground:

> "Neurosine is presented in a very palatable and agreeable form and can be administered for an indefinite time without untoward by-effects as so often attends the use of the commercial bromides. In order to secure lasting benefits the treatment should be extended over a long period of time."

The evident implication here is that the recognized drawbacks of bromid medication are due to impurities present in the commercial bromids and that the teachings of modern medicine with regard to caution in the use of bromids do not apply in the case of Neurosine.

The assurance is offered:

> "Neurosine contains no chloral, morphin or other objectionable drug—a fact of the utmost importance when administering medicines to neurotic women."

> "As a nerve-calmative and sleep-producer nothing can excel Neurosine . . . It should be borne in mind that this preparation contains no opium, morphine, chloral or habit-forming drugs . . . Neurosine being a harmless remedy is especially indicated for neurotic individuals."

Apart from cannabis indica, Neurosine contains no efficient hypnotic. Cannabis indica is a dangerous drug, whose administration to "neurotic individuals" is by no means free from danger—especially when it is given under a proprietary name that carries no warning of its presence.

Here is another recommendation—this time for chorea:

> "All authorities recommend the bromides, hyoscyamus and cannabis indica in this disease. These remedies are all combined in Neurosine, the ideal calmative for both children and adults."

On the contrary, practically "all [medical] authorities" will admit that it is undesirable to keep a child under the influence of bromids if this can be avoided. Such treatment is mentioned only for use as a last resort in extreme cases. Hyoscyamus and cannabis indica are mentioned in connection with chorea by few authorities, and then merely as probably valueless.

Not content with recommending the promiscuous use of this already too complex mixture, the Dios Chemical Company advises physicians to combine it with iron, when chalybeate and tonic effects are to be combined with "a nervine," with acetanilid for "irritable cough," headache and neuralgia, with antipyrin in asthma and with Dioviburnia—another Dios nostrum—in all female ailments. Neurosine and its congeners violate practically all the principles of modern therapeutics.

Germiletum

Germiletum is a member of the large class of alkaline antiseptic solutions with excessively complex formulas. In this case not only is the formula complex but also the Dios Chemical Company finds it impossible even to assign a constant composition to it—at least the "formulas" which appear on the different styles of Germiletum labels and advertising circulars vary greatly.

The company says:

> "We appeal only to the Doctor's judgment of his estimation of the formula."

> "Doctor you will readily determine from the formula the class of cases in which you have a right to expect satisfactory results."

Yet the "formulas" given present so great a variety and such confusion that it is not clear even to a chemist just what the Dios Company wants the medical profession to regard as the composition of Germiletum.

The following statements of "composition" have appeared at various times:

1. In an advertising circular sent out some time ago:

$$\text{“}[HBF_4 + BOH\ (OC_6H_4\ COOH)_2 + BOH\ (OC_6H_3COOH)_2 + C_3H_5BO_3 + CH_2O + C_{10}H_{14}O + C_{10}H_{20}O + C_{24}H_{28}N_3Cl.]\text{”}$$

2. In advertising circulars which have been received of late, being wrapped with a sample package and with the "large size" trade package:

$$\text{“}[C_7H_6O_2 + H_3BO_3 + C_3H_5BO_3 + (CH_2O)_3 + C_{10}H_{20}O + C_{10}H_{14}O + C_2H_6O]\text{”}.$$

3. In another advertising circular:

> "Germiletum is a slightly alkaline chemical solution of Borohydrofluoric Acid, Borosalylbenzoic Acid, Boroglycerine, Formaldehyde with Menthol, Thymol and Antiseptic Aromatics."

4. On the label of a sample package sent through the mails during 1914, and on the label of a "small size" trade package purchased in 1914:

> "FORMULA.—Borohydrofluoric Acid, Borosalylbenzoic Acid, Boroglycerine, Formaldehyde with Menthol, Thymol, Amyl Acetate and other Antiseptic Aromatics."

5. In the circular which was wrapped around the sample package referred to above, and around the "large size" trade package purchased at the same time that the "small size" package was bought:

> "Germiletum is a slightly alkaline chemical solution of Borobenzoic Acid, Boroglycerine Formaldehyde, with Menthol, Thymol and other Antiseptec [*sic*] Aromatics."

6. On the sample package, on the "small size" trade package and on the wrappers of the "large size" trade package:

> "Alcohol 18 per cent.; Formalin 3/4 M. per oz.; Amyl Acetate 1/3 M. per oz." (also written "Acetate Amyl.")

The label on the large trade package states that Germiletum contains "Formalin ½ M. per oz."

One and all of these various formulas spell mystery. The existence of some of the constituents is problematic; even if the theoretical possibility of such combinations be conceded, some of them could not exist in Germiletum, for they would be broken up by the alkaline fluid. As illustrating the contradictions which the formulas present: While the wrapper of the "large size" trade package claims that Germiletum contains ¾ minims Formalin (Formalin is a proprietary name for a 40 per cent. formaldehyd solution) the label on the bottle claims only ½ minim. Again, while the composition expressed in chemical symbols asserts that "H_3BO_3" (boric acid) is a constituent of Germiletum, the "formula" which follows it states that Germiletum has an alkaline reaction; hence it cannot contain much boric acid. Finally, the "small size" bottle of Germiletum purchased at the same time as the "large size" bottle and also the label of a sample package sent through the mails to a physician in 1914, give as a constituent "Borohydrofluoric Acid," which is mentioned neither on the label of the "large size" trade package nor in the pamphlet wrapped around it. The only information which these contradictory "formulas" can convey to a physician is that Germiletum is an unscientific, varying mixture of many drugs.

A trade package, having the name "Germiletum" blown in the glass, bears on the label recommendations for its use in the treatment of "catarrh," "Gastritis, Stomatitis, Gastric and Intestinal Catarrh," "Leucorrhea and Uterine Diseases," "Hemorrhoids," "Whooping Cough," "Tonsilitis and other forms of sore throat" and "Eczema."

The following statement on the label is designed to induce physicians to place false confidence in Germiletum to the danger of their patients:

> "The lying-in-room should be thoroughly sprayed with Germiletum. Can be relied upon to destroy the living particles which so generally constitute contagion."

This claim, as well as the assertion which appears on the label of a sample package and of the "small size" trade package that it is "PAR-EXCELLENT IN OBSTETRICAL PRACTICE" is almost criminal, as Fussell[1] has said, since to depend on any preparation of this sort is to court disaster.

The booklet around the trade package makes the claim that Germiletum "is the best antiseptic"—evidently largely because it is claimed to be "the blandest of all"—and that it is "thoroughly germicidal" and even that it is "the best disinfectant obtainable." It also contains such unwarranted and misleading claims and suggestions as:

> ". . . preparatory to all operative work—Germiletum should be used freely in spraying the atmosphere . . ."
>
> "Operative wounds, whether large or small, can be rendered thoroughly antiseptic by freely spraying them with Germiletum. . . ."
>
> ". . . it may be given internally in many dyspepsias and in all zymotic diseases. . . . In such conditions Germiletum is the ideal internal antiseptic and disinfectant."

In the present advertising, no evidence whatever is offered for the value of Germiletum, the Dios Company contenting itself with unsupported claims and cant phrases such as

> ". . . the truth is only reached through a final appeal to intelligent practical experience."

In the old circulars only crude, uncritical and meaningless tests to establish the antiseptic value of Germiletum are reported and none whatever as to its germicidal action. In the advertising matter sent out some time ago, for instance, were given "Microscopical, Bacteriological and Chemical Tests, Comparing Germiletum with Carbolic Acid." These tests have no value whatever, unless it be to show the worthlessness of the preparation. This is particularly true as regards a series of experiments on "Germiletum as a Preventive of Lactic Fermentation," in which one part of Germiletum in thirty parts of milk did not prevent fermentation. Such effect as indicated is probably due to the formaldehyd present. The tests show the absurdity of using the preparation for internal and external purposes. The referee challenges the therapeutic claims on the basis that they are extravagant and unsubstantiated. (The Chemical Laboratory of the American Medical Association reports that the alkalinity of Germiletum corresponds approximately to a 1 per cent. borax solution.)

Dioviburnia

Dioviburnia, another Dios nostrum, according to the label, has the following composition:

> "Every fl. oz. contains 3-4 dr. each of the fl. extracts, Viburnum Prunifolium, Viburnum Opulus, Dioscorea Villosa, Aletris Farinosa, Helonias Dioica, Mitchellae [*sic*] Repens, Caulophyllum Thalictroides, Scutellaria Laterifolia." [Lateriflora?—Ed.]

Further, according to the label, Dioviburnia contains 18 per cent. alcohol. If this statement is correct then the "formula" is false, for the fluid extracts named contain from 25 to 73 per cent. of alcohol. As—according to the "formula"—these fluid extracts constitute three-fourths of Dioviburnia, the average alcohol-content in the whole mixture must of necessity be much above 18 per cent.[1] According to the makers, Dioviburnia is "unexcelled" for:

> "Amenorrhea, Dysmenorrhea, Leucorrhea, Puerperal Convulsions, Prolapsus Uteri, Menorrhagia, Threatened Abortion, Parturition, Subinvolution, Miscarriage, and a general relaxed condition of the uterus and appendages, together with the various aches and pains peculiar to women."

Around the sample bottle of Dioviburnia is wrapped a booklet entitled "A Treatise on Uterine Diseases and Obstetrical Hints," said to be "For the Profession Only." The booklet has been prepared, physicians are told, to present "some very valuable suggestions" regarding the treatment of female disorders and the attention of the medical profession is "earnestly" called to the "very remarkable medicine," Dioviburnia. Further, it is said that Dioviburnia was devised by the Dios Chemical Company because there was an "absolute necessity" for some really efficient internal treatment in female diseases. The company backs up its statements by such claims as:

> "The most valuable preparation, therapeutically, ever offered."
>
> "[Contains] every essential for toning up the female organs of generation, and relieving pain."
>
> "A general and special tonic, antispasmodic and invigorating cordial."

While the company directs the attention of physicians to the "well-known, therapeutical effects of each individual constituent" of Dioviburnia, there is in reality little positive evidence regarding the action of any of the drugs contained in the nostrum. Most writers on materia medica do not even mention these drugs and the few who do discuss them, either question or deny their medicinal value. But if every drug claimed to be present in Dioviburnia had some actual demonstrated therapeutic properties, it still would be impossible to predict the action of such a combination in the many and varied conditions for which it is exploited. Certainly there is no warrant for such statements as:

> "In Painful Dysmenorrhea [*sic*] Dioviburnia is especially indicated, and its continued use will invariably give relief."
>
> "In cases of Leucorrhea of long standing, Dioviburnia, together with local treatment, invariably gives relief."
>
> "Dioviburnia is efficient in cases of subinvolution; it cures by its *tonic effects* . . ."

The effects of the drugs alleged to be present in Dioviburnia are not such as to justify the hope of either "cure" or "invariable relief." In a way the Dios Chemical Company seems to recognize the inefficiency of Dioviburnia since it frequently suggests that it be used in combination with drugs of known value; but it ascribes all favorable results to its own product:

> "In chronic constipation fluid extract of cascara sagrada aromatic may be combined with Dioviburnia."
>
> "In cases of habitual abortion, depending on syphilitic taint, a prescription containing the following should be used during the entire pregnancy:

℞	"Hydrarg. Chlor. Corros	gr. 1
	"Potass. Iodid	dram 1
	"Dioviburnia	*ounces* 16"

> "An Anemic or Chlorotic patient, suffering with absence of the menstrual flow, should take DIOVIBURNIA combined with Iron."
>
> "In leucorrhea depending on endocervicitis, hot astringent douches once daily should be given. Local applications of iodin are useful in chronic conditions. Internally, Dioviburnia promotes healing."
>
> "Rest in bed, hot douches of a one-half per cent. solution of compound cresol solution and Dioviburnia internally, a teaspoonful every 3 hours will rarely fail to cure endometritis in a few days."
>
> "In specific vaginitis, a solution of potassium permanganate (1 to 1000) should be used as a douche twice daily. Internally give the following:

"Sodii benzoate	½ ounce
"Dioviburnia	16 ounces

> "M. sig., Teaspoonful every three hours."
>
> "Prolapsus Uteri is benefited, and often cured, by DIOVIBURNIA combined with local treatment in the shape of tampons, pessaries, electricity, etc."

---

[1] Fussell, M. H.: Dangers of Certain Ethical Proprietary Preparations to Both Physicians and Public, The Journal A. M. A., Oct. 7, 1911, p. 1196.

[1] Five of these fluidextracts have their alcohol-content determined by the Pharmacopeia or National Formulary. Three are not recognized and hence their alcohol-content is not defined by law. The alcohol-content of the mixture of fluidextracts said to be in *Dioviburnia* has been kindly furnished by five leading pharmaceutical houses. If the lowest alcohol-content of the several fluidextracts is made the basis of calculation, Dioviburnia should contain at least 30.75 per cent. of alcohol, or more than half as much again as the amount declared on the label.

If Dioviburnia will cure specific vaginitis, anemia, etc., so will a cobblestone make excellent soup. All that is necessary in the former case is to add certain potent drugs that might be indicated in the pathologic conditions mentioned and, in the latter case, to combine suitable amounts of beef, chicken, green turtle or vegetables, with herbs and other seasoning.

Palpebrine

According to the Dios Chemical Company, Palpebrine is "A Reliable External Ocular Antiseptic" having, it is said, the following composition:

> ". . . each fluid ounce contains 1/116 grain Sulphate of Morphia, 1/7 grain Sulphate of Zinc, 1/11 grain Bi-Chloride of Mercury, 5⅜ grains Boric Acid, ¾ grain Salicylic Acid."

The essential virtues ascribed to Palpebrine, according to its makers, are its harmlessness and its therapeutic efficiency due, presumably, to its complex composition:

> "Attention is called to the constituents of this formula, each one of which is used by ophthalmologists. Their combination in Palpebrine is such as to blend their action in a very happy manner. Palpebrine acts as an antiseptic, an irritant, an astringent, and a nerve tonic to the mucous membrane of the eye."
>
> "Palpebrine is superior in its action to the remedies now in use. It contains all the constituents of Aqua Conradi . . . But to these are added a number of other agents which will prove it to be of much greater value and give it a broader field for action."

In all external afflictions of the eye the free use of Palpebrine is suggested in such statements as:

> "They [general practitioners] will therefore gladly receive from our hands an efficacious preparation which may be used with perfect safety."
>
> "The name of our preparation—Palpebrine, is derived from the Latin *palpebra,* the eyelid, and is well fitted, as it designates at a glance the sphere of action of Palpebrine."
>
> "With the assistance of Palpebrine the general practitioner can successfully treat all cases of external eye disease ordinarily encountered in his practice."

One of the members of the Council staff of clinical consultants calls attention to the fact that much vitally valuable time might be lost in a case of iritis, for example, which being unrecognized, should be treated with Palpebrine on the strength of the Dios Chemical Company's advertisements. Even more dangerous is the recommendation of Palpebrine for the prevention of ophthalmia in the newborn, especially as this recommendation is coupled with an attempt to discredit the established treatment with silver nitrate solution:

> "The use of severe remedies for this purpose has been discarded by most physicians. . . ."

While it is doubtless true that ophthalmia neonatorum may be averted by other drugs than silver salts, it is utterly unjustifiable to suggest that the established method of treatment by means of silver salt irrigations has been generally discarded.

[Editorial Note.—The four nostrums mentioned above have been grouped together for publication to call attention to one phase of the proprietary business. A fact not mentioned in the Council's report is that these nostrums are manufactured and promoted by a concern that belongs to a type we have often designated "pseudo-chemical" companies. By this is meant companies that are not in the legitimate business of pharmacy or chemistry, but organized to exploit one, two or in some instances half a dozen proprietaries. "Patent medicines" are exploited by this class of "companies." The Dios Chemical Company is not a chemical company, except in name. J. H. Chambers, the founder so far as we can learn, never claimed any special knowledge of chemistry, pharmacy or medicine. The officers at the present time are: J. H. Chambers, president; M. E. Chambers, vice-president; Leslie T. Chambers, treasurer, and Arthur Chambers, secretary. M. E. is the wife of J. H., and Leslie T. and Arthur are sons.

This is simply one illustration of the fact noted above. Some physicians have been and are prescribing nostrums originated, manufactured and advertised by laymen who are not in the legitimate pharmacy business. In addition, such physicians have been accepting the statements of laymen, not only as to the composition of the nostrums, but as to their use. In every state the practice of pharmacy is regulated by law: before assuming the responsibility of compounding medicines a druggist must have studied and passed an examination in pharmacy. Public safety demands and the law requires it. There are some doctors, however, who will allow laymen who are not chemists, pharmacists nor physicians to formulate and compound a prescription and tell them what it is good for and how to use it.

The Dios Chemical Company is not an isolated instance: we have already referred to some; we shall take occasion to refer to others in the future. That such concerns flourish is a reflection not so much on the shrewd laymen who exploit the medical profession—and through it the public—as it is on the physicians who cast their scientific training to the winds and permit themselves to be thus exploited.]

CORRECTION

Quantity of Iodine in Iodotone

In this department of The Journal for Dec. 12, 1914, p. 2149, under the heading "Iodotone" the statement is made: "Iodotone, sold by Eimer and Amend, New York, is stated to be a solution of hydrogen iodid (hydriodic acid) in glycerin and to contain 1 grain of iodin per fluid ounce." This should read—"one grain to each fluid dram."

Correspondence

Military Surgery

To the Editor:—Some statements in Dr. Hoguet's "Observations on Military Surgery in the Early Weeks of the War" (The Journal, Dec. 19, 1914, p. 2194) purporting to represent a contribution based on his experiences in the American hospital at Neuilly-Paris, should not be allowed to remain unchallenged.

Dr. Hoguet has favored us with more than his personal experience, by familiarizing us with frontal organization and transport, but, unfortunately, does not correlate these with his experience in Paris, which city must be looked on as basal as far as medical aid is concerned, thereby failing to allow the uninitiated an insight into the real problems of modern war surgery, for a few operations performed at base hospitals have scarcely anything in common with military surgery in the more restricted sense of the word.

Dr. Hoguet further says, "When a strong bone, such as the humerus or femur, is struck by a bullet within its zone of maximum speed (5,465 yards), one of two things may happen: Either the bone is cleanly perforated—and this is very rare—or else it is completely shattered," and plainly shows that he either is not familiar with ballistics or has made an error in copying from whatever source he obtained his information. The German rifle is sighted up to 2,187 yards, and if even the best German sharpshooter, by elevating his rifle about 45 degrees, were to fire at me at 5,465 yards (over 3 miles!) I would have the choice of stepping out of the way, since it would require over half a minute for the missile to reach the target, if it would reach it at all, or catching the bullet with my bare hand as a souvenir of modern medicomilitary literature.

The fact is that both near and distant shots bring about the so-called "butterfly" fractures with this difference, that the closer the range the smaller the fragments, which, when the live force is near its maximum (there is no such a thing as maximum since the muzzle velocity loses practically after encountering air friction), may amount to extensive comminution. Gunshot wounds are governed by a fixed, immutable law (Newton's) and while the density (air and liquid content) of the tissues may result in pathologic variations from a mere puncture to extensive laceration and destruction, there is but one law governing any and all injuries.

This law, however, has very little to do with the clinical course of an injury, but the military surgeon will be in a position so to apply the laws of bacteriology as not only to explain but to control most infections. One cannot but express wonder at a paragraph in the article under consideration when the author endeavors to seek an explanation why infected compound fractures of the arm heal better than like injuries of the thigh. Dr. Hoguet indulges in speculation about better supply of blood and easier drainage. Any one familiar with the elements of anatomy knows that the thigh can show at least as good a blood supply as the arm, and when it comes to the question of effective drainage, I cannot recall that the mere thickness of a group of muscles ever interfered with the introduction of a drainage tube. If the author had but considered a simple experience on the battlefield, namely, that a soldier hit in the arm can immobilize his limb by pinning his affected sleeve to his tunic and still be about, and thereby retain good vitality, especially during transport, while a combatant sustaining a like injury in the thigh must necessarily remain recumbent and often suffers during transport from ineffective immobilization (oh, for that significant little word "rest" in military surgery!) thereby sustaining additional trauma, if not contact infection, easily resulting in a veritable ideal condition for "life-saving" amputation all speculation would have proved unnecessary.

In this respect at least the experience of the present war in Europe is not likely to bring out anything not already well known to military surgeons.

Gustavus M. Blech, M.D., Chicago.

Bureaus of Information for American Postgraduate Study

To the Editor:—While recently in New York, I noticed the large number of physicians seeking postgraduate work who daily arrived at the various clinics and hospitals and who, being unable to go to Europe, had turned to the home clinics in the United States. No doubt all of our large centers have received their share of these postgraduate students and workers.

It occurred to me that each large city having postgraduate facilities or extensive medical centers might do well to have a centralized and well-organized bureau of information for the benefit of the stranger, where the newly arrived physician might obtain, with the least loss of time, such information as would assist him in locating the particular line of clinical and special instruction desired in the shortest time.

In New York I saw a number of physicians visiting a number of hospitals, clinics and instructors before finding the most adaptable place for their desired studies, and doing this at an enormous expense of time, when one considers that usually the busy physician has short enough time in the postgraduate centers.

I would suggest a get-together movement on the part of the leaders in post-graduate schools to establish a bureau of medical information, either as a part of the medical society or part of the medical committee of the chamber of commerce, and as soon as such is developed, thoroughly advertise the fact to the profession. A small registration fee might be charged the visiting physicians, for which their problems might be taken under advisement and assistance given in the matter of finding appropriate living accommodations within easy access of the clinic or hospital to be attended.

Physicians in New York usually feel that the stranger requires several days before he becomes oriented in the city. I know I would have greatly appreciated such guidance and direction as I herein suggest.

By publishing this letter you may stimulate a movement which I feel would be in accordance with American advance in the systematic upbuilding of our clinical centers, whose value is certainly second to none, even European centers of overcongestion, which are at present inaccessible.

C. O. Jaster, Elyria, Ohio.

Formula for Cleaning Glassware

To the Editor:—I wish to call attention to the fact that I have had great success during the last few months in cleaning stained slides and glassware by using a preparation consisting of equal parts of a 6 per cent. solution of sodium hydroxid and a 2 per cent. solution of calcium carbonate. Boil the slides in this mixture for one minute. The slides are then rinsed in cold water and wiped.

Abe H. Kaplan,
Laboratory Department,
City and County Hospital, St. Paul.

ETHER DRINKING

To the Editor:—Please give me information concerning the drinking of ether as a habit. A. R. Y.

Answer.—The use of ether as an intoxicant, referred to in a few text-books and some journals, is a rather uncommon practice. Most of the reports relate to observations of this habit in Ireland, where it is limited to restricted well-defined districts and in which it is almost universally practiced. Ether drinking began in these places about the middle of the last century. A certain formality is observed by some drinkers, such as the taking of a mouthful of cold water before and after the drug is swallowed; the ether is taken both diluted and pure. The real habitué, however, scorns the use of water as well as the diluted drug. The quantity taken for one debauch is from 2 drams to 1 pint. Just as in the case of alcoholic drinks, the tolerance to the drug and the amount to produce intoxication vary.

The effects are similar to those of alcohol, but they come on and wear off more rapidly, leaving little or no discomfort; hence the tendency to repeat the intoxication, which is regarded by some as pleasurable, so that there may be as many as half a dozen to twenty periods of ether-drunkenness during twenty-four hours. Quantities of ether as large as 1 liter a day are mentioned by various writers, as being consumed in this way. There is a very interesting report by

Ewald of an "ether breather," a well-educated man who was able to demonstrate and analyze the immediate effects of the drug, on his own mental faculties in particular. Insanity is not directly connected with the habit by those who have observed the consequences of this exceptional form of drunkenness. The effect on health seems to be limited to chronic gastritis and dyspepsia. However, several sudden deaths in the "ether area" of Ireland not otherwise explained have been attributed to ether drinking. Sometimes conditions very similar to those of chronic alcoholism are observed. One peculiar danger alleged to ether drinkers is that of setting themselves on fire, as, for example, in lighting a pipe.

It appears that very little is known by pathologists of the harmful effects on the tissues by chronic ether intoxication. Atrophy and sclerosis of the brain and of the liver, such as occurs in chronic alcoholism, have not been observed. It has been suggested that the detrimental effects will be more evident in the descendants of ether drinkers, the larger contingent of whom, in Ireland at least, is represented by robust men.

ACTION OF HEXAMETHYLENAMIN

To the Editor:—1. In what conditions is hexamethylenamin indicated?

2. (*a*) If it requires a certain percentage of acid to break it up into formaldehyd, are the body fluids in cholecystitis and organic nervous diseases, as herpes zoster, acid? (*b*) If not, has it any therapeutic value in such conditions?

3. Why is it used after all penetrating injuries of the brain and cord and before all operations on them?

Gerald H. J. Pearson, M.D.

Answer.—1. When it is desired to destroy or prevent the multiplication of micro-organisms in the urine.

2. (*a*) No. (*b*) Not so far as known.

3. When used in these conditions, it is on the false assumption that it can be active in tissues which are not acid in reaction. There is no evidence warranting its use in such conditions.

CAMPHORATED OIL IN ABDOMINAL SURGERY

To the Editor:—I should be much obliged for any information on the use of camphorated oil locally in the peritoneal cavity after abdominal interventions.

E. F. Rodriguez, M.D., Sagua la Grande, Cuba.

Answer.—The following articles may be referred to:

REMOVAL OF RUST FROM INSTRUMENTS

To the Editor:—A correspondent asks for a solution to prevent instruments from rusting (The Journal, Jan. 2, 1915, p. 72). If among instruments he includes hypodermic needles, there is nothing more serviceable to prevent rusting and consequent plugging than equal parts of almond oil and alcohol. This may be kept in a covered glass dish or a wide-mouthed bottle, and the needles allowed to remain in the solution when not in use. They may easily be removed with tissue forceps, the oil allowed to drain, and what of it that remains in the caliber of the needles can be cleared out with a jet of alcohol. Solutions containing bacterins and vaccines seem especially prone to produce plugging of needles, and this annoyance can be prevented absolutely and the life of the needle indefinitely prolonged by the use of the almond oil-alcohol mixture.

Bernard Wolff, M.D., Atlanta, Ga.

Medical Education and State Boards of Registration

COMING EXAMINATIONS

California: Sacramento, Jan. 12, 1915. Sec., Dr. Charles B. Pinkham, 727 Butler Bldg., San Francisco.

Illinois: Chicago, Jan. 13-15, 1915. Sec., Dr. C. St. Clair Drake, Springfield.

Indiana: Indianapolis, Jan. 12-14, 1915. Sec., Dr. W. T. Gott, State House, Indianapolis.

Iowa: Des Moines, Jan. 19-21, 1915. Sec., Dr. Guilford H. Sumner, Capitol Bldg., Des Moines.

Kansas: Topeka, Feb. 9-11, 1915. Sec., Dr. H. A. Dykes, Lebanon.

New Mexico: Santa Fe, Jan. 11, 1915. Sec., Dr. W. E. Kaser, E. Las Vegas.

New York: Albany, Buffalo, New York, Syracuse, Jan. 26-29, 1915. Mr. H. H. Horner, Chief, Examination Division, State Education Bldg., Albany.

Oklahoma: Oklahoma City, Jan. 12-14, 1915. Sec., Dr. John W. Duke, Guthrie.

South Dakota: Pierre, Jan. 12, 1915. Sec. Dr. P. B. Jenkins, Waubay.

Vermont: Montpelier, Jan. 11-13, 1915. Sec., Dr. W. Scott Nay, Underhill.

Wisconsin: Madison, Jan. 12-14, 1915. Sec., Dr. John M. Beffel, 3200 Clybourn St., Milwaukee.

Preventive Medicine at the University of California

Following the inauguration of the work of the George Williams Hooper Foundation for Medical Research, for the maintenance of which $50,000 per annum is available, the University of California, Medical School, is contemplating the development of a course in preventive medicine which will lead to the degree of Graduate in Public Health. To secure this degree it is planned that students must have satisfactorily completed one of the three following courses:

(*a*) The four years' course in the college of Letters and Science, beginning with the junior year, two years counting toward the degree of A.B., to be followed by two years of graduate work; or

(*b*) A two years' course in the Graduate School following the receiving of the degree of B.S. by students who have completed the four-year undergraduate curriculum in sanitary engineering; or

(*c*) A course for students in the University of California, Medical School, beginning in the second half of the fourth year (that is, the second graduate year) of the regular curriculum in the Medical School, and continuing for a year and a half to the end of the third graduate year, at which time the degree of M.D. in the Medical School and the degree of Graduate in Public Health in the College of Letters and Science would be conferred.

There are now nine medical colleges which have established graduate courses in public health.

Hospital Intern Year Required

A letter from the dean of Northwestern University Medical School states that at the quarterly meeting of the board of trustees, held recently, the recommendation of the medical school was adopted, that an additional year of hospital work be made part of the medical work for the course for students entering for the session of 1915 and thereafter. This is the fifth medical school to adopt this requirement. The complete list and the sessions when the requirement became effective, or will become effective, are as follows:

	Session of
University of Minnesota Medical School	1910-11
Leland Stanford Jr. University School of Medicine	1914-15
Rush Medical College (University of Chicago)	1914-15
University of Vermont College of Medicine	1915-16
Northwestern University Medical School	1915-16

One state licensing board, that of Pennsylvania, now requires that every candidate to be eligible for a license to practice medicine in that state must have served at least one year as an intern in an approved hospital. The requirement became effective in 1914.

California June Report

Dr. Charles B. Pinkham, secretary of the Board of Medical Examiners of the State of California, reports the written examination held at Los Angeles, June 16-19, 1914. The total number of subjects examined in was 9; total number of questions asked, 90; percentage required to pass, 75. The total number of candidates examined was 88, of whom 60 passed, including 11 drugless practitioners, and 28 failed, including 16 drugless practitioners. One hundred and nine candidates were licensed through reciprocity. The following colleges were represented:

Book Notices

Diseases of the Skin, Including the Acute Eruptive Fevers. By Frank Crozer Knowles, M.D., Instructor in Dermatology, University of Pennsylvania. Cloth. Price, $4 net. Pp. 546, with 213 illustrations. Philadelphia: Lea & Febiger, 1914.

This book belongs to the manual class of text-books; it is *midway between the quiz-compend and the complete treatise.* A successful manual in dermatology should appeal to a large group of students and practitioners, and demands special skill and judgment in the selection and presentation of the subject-matter. The facts chosen from the vast field of dermatologic knowledge must be adequate without excess, and must be clearly and concisely set forth. The author in this instance has met these requirements in part, but not wholly. His selection of material to be presented is scarcely open to criticism, and good judgment is shown in the relative emphasis given the various subjects. The general scheme of presentation is excellent, and in certain respects original; and conciseness is observed in the discussions. There is present, however, a lack of clearness of statement in so many places as to suggest hasty preparation and careless proofreading. A few examples may be cited. In the first paragraph of the preface appears: "In order to make the book more complete, not only the exanthemata are included, but also the acute eruptive fevers that are constantly or occasionally accompanied by a dermal outbreak." In the text proper: "The exact cause of this affection is unknown, but it is probably of toxemic origin, either due to some intestinal toxin or of a bacterial nature." "Erythema multiforme is distinguished from urticaria by the more lasting character of the lesions, a few hours or minutes in the one and days in the other." "Pellagra is a constitutional disease exhibiting a cutaneous outbreak which is chiefly of the exposed surfaces, gastro-intestinal and nervous symptoms." "Erythema paratrimma is the title employed, now almost obsolete, to signify the resultant erythema from the pressure of the prone position preceding a bedsore." A scar, correctly defined in one place, is given elsewhere as "a new formation of skin which replaces tissue loss." Errors in grammatical and rhetorical construction and in the choice of words, while detracting from the general effect of the whole, may not impair validity of statement and can easily be corrected in a subsequent edition. The author will find very few in agreement with him in his classification of Oriental sore under diseases caused by vegetable organisms (cocci). He is bold also in putting syphilis under the same category (spirilli), considering the prevailing opinion as to the *Treponema pallidum*.

A Medical Dictionary for Nurses, Giving the Definition, Pronunciation and Derivation of Terms Used in Medicine, Together with Supplementary Tables of Weights, Measures, Chemical Symbols, etc., Arranged with Special Reference to Use by Nurses. By Amy E. Pope. Cloth. Price, $1. Pp. 288. New York: G. P. Putnam's Sons, 1914.

In addition to giving the definition, pronunciation and spelling of words, this book gives in many cases a description of the uses of substances and the course of diseases. For example: Under tuberculin, the various tuberculin reactions are described; under typhoid, after the statement that it is an infectious disease due to infection with the *Bacillus typhosus*, the symptoms are given and also the complications. The book also includes a list of abbreviations, a table of chemical symbols, a table of the elements, a classification of the poisons and their antidotes, frequently used prefixes and suffixes, tables of weights and measures, methods of reckoning the amount of drug necessary in making solutions, and a table of average composition of common American food products. There are errors, such as the use of "tubercular" for "tuberculous" and "apnoia" for "apnoea," which should be corrected in future editions.

Diseases of the Rectum and Anus. A Practical Handbook. By P. Lockhart-Mummery, F.R.C.S., Senior Surgeon to St. Mark's Hospital. Cloth. Price, $3 net. Pp. 348, with 102 illustrations. New York: William Wood & Co., 1914.

This is the newest of the many books in the field of proctology. It is a handy little volume divided into twenty-three chapters. Useless discussions are avoided, only such methods of treatment which the author has tested and found worth while are described, and in many instances illustrative cases are cited which add greatly to the value of the book. The medicinal treatment of each disease is discussed thoroughly and given preference over surgery when it should be, although the author is a surgeon of prominence. The many prescriptions given will prove useful to the general practitioner as well as to his patient who is seeking relief from his symptoms while taking other treatment under advisement. Much more might be said in praise of the book, but the points mentioned will suffice to indicate that it may be recommended as being worth while.

California and the Far West. Suggestions for the West-Bound Traveler. By K. E. M. Dumbell. Cloth. Price, 75 cents. Pp. 198. New York: James Pott & Co., 1914.

A better—at least a more descriptive—title for this book would be "Suggestions to Those Who Are Proposing a Trip to the Western Coast and Alaska." It mentions the six main transcontinental routes from the Atlantic to the Pacific coast, and gives brief descriptions of the important places—parks, glaciers, canyons, mountains, rivers, lakes, towns, etc.—that may be taken in on the different routes. The descriptions are not sufficiently full to deserve the designation, but must be regarded as suggestions only. There is a list of the principal hotels with rates, and a small map of the western states. The book will prove helpful to those who are arranging to go to the San Francisco and San Diego expositions, which includes those of our readers who expect to attend the next meeting of the American Medical Association. Its special helpfulness lies in the fact that it gives different points of interest on the various routes.

Periodical Examination and Preventive Medicine.—Preventive medicine in order to be of the greatest service to mankind must insist upon the medical examination of every citizen once or twice a year. It is the only thing which will reach the root of the evil.—Victor C. Vaughan, *Journal Michigan State Medical Society*.

Miscellany

Quarry Accidents in the United States in 1913

Although the number of deaths from accidents in quarries in the United States in 1913 was less by about 14 per cent. than for the year 1912, it is still unnecessarily high and does not compare favorably with the records of foreign countries. According to a recent report of the Bureau of Mines[1] the number of men employed in the quarry industry in 1913 was 106,278 as compared with 113,105 in 1912, but on account of the greater number of days worked in 1913 the record for that year exceeds by 800,000 days' labor the record of the previous year. The total number of men killed in 1913 was 183, a fatality rate of 1.72 per 1,000 as against 1.88 in 1912. In the coal industry among the 747,644 men employed in 1913 the fatality rate was 3.73 per 1,000 men employed, and in the metal mines among 193,088 men it was 3.54 per 1,000. It is to be expected that these rates would be higher than that of the quarries where the work is carried on chiefly or altogether in the open, yet it is interesting to note that the fatalities in the coal mines due to falls of roof, wall rock or coal in 1913 amounted to 45.38 per cent. of all fatalities, and in metal mines to 36.16 per cent., while in the quarries falls of rock or overburden caused 20.76 per cent. of fatalities, a seeming disproportion in consideration of the apparent risk.

It is said that the principal hazards of quarrying appear to be about equally divided with reference to explosives, falls of quarry material, and haulage. Accidents from these three causes are said to represent nearly two-thirds of all deaths. In France the mortality rate from quarry accidents is said to be about 1 per 1,000 men employed. In 1912 it was only 0.91. In Great Britain the average for ten years was about 1.09 per 1,000 men employed, and in 1913 it was only 1.05. The fatality rate in the United States in open quarries, with ample light and air and with no risk of roof falls, is said to be greater than in some of the coal or metal mines in foreign countries. This is attributed to less stringent regulations and less systematic inspection. Although percentages of serious and slight injuries are given, the uncertain method of rating or reporting injuries in the different states or in the quarries makes their exact value doubtful. A uniform method should be adopted, as advocated in the report.

Frontal Sinus Suppuration

Many cases of chronic suppuration of the frontal sinus may be permanently cured by intranasal treatment whereby the anterior and upper portion of the middle turbinate and some adjacent cells are removed. Many other cases, according to Lothrop (*Annals of Surgery*, 1914, lix, 937), will not yield to this treatment. The operations in present use are (1) intranasal and (2) extranasal.

Most authorities agree that the intranasal effort to enlarge the vicinity of the ostium of the sinus is attended with unnecessary risk. In the external operations the facial or orbital wall of the sinus or both are removed, and the more radical, such as the Killian operation, removes also a portion of the nasal process of the superior maxilla and lacrimal bone. These operations strive to obliterate the sinus and there is subsequent disfigurement, varying according to the type of operation.

The establishing and maintaining of adequate drainage is difficult because of the anatomic relations in the vicinity of the ostium. The principle of the Killian operation, Lothrop believes, is wrong because the bony support afforded by the nasal process of the superior maxilla and lacrimal bone is removed and thereby the soft parts are drawn in subsequently and thus the region is narrowed. In the smaller sinuses, provided the patient does not object to the deformity, the result may be satisfactory.

---

[1] Quarry Accidents in the United States During the Calendar Year 1913. Technical Paper 92, U. S. Bureau of Mines.

The steps in Lothrop's operation are as follows: A small bony opening is made in the facial wall just above the nasal process; a small probe is passed through the ostium into the nasal cavity and left there while, by means of small curets at the start, and subsequently the use of burr drills, the neighboring anterior ethmoid cells and the nasal process of the frontal bone are removed; then the thickened mass of bone which exists at the region of articulation between the frontal bone above and the nasal bone, and the nasal process of the superior maxilla are so thinned as to leave only a thin shell. "This removal," says Lothrop, "can be accomplished only by means of burr drills introduced through the nose with the burr in sight through the opening in the facial wall." Furthermore, he believes that there is no objection and that it is advisable, even when only one sinus is involved, to break through the interfrontal septum and remove in the same manner the corresponding portion of the floor of that sinus. The removal includes also a portion of the nasal septum for a distance below the interfrontal septum. By this procedure a surprisingly large opening is obtained and an instrument entering either nostril can be passed into either sinus and swept across from one side to the other. The external wound is closed. Thus obstinate fistulas may be cured at once. As after all operations on the frontal sinus, a certain amount of subsequent intranasal treatment is necessary in order to control the growth of granulation tissue.

In cases in which, as a result of previous operations, the bony structures mentioned above have been extensively removed followed by excessive granulation tissue formation causing early obstruction, successful results have been obtained by epidermizing the sinus after the manner described in The Journal, July 25, 1914, p. 352.

Sanitary Survey of State

Surgeon Carroll Fox, U. S. P. H. S., Washington, who has been making a state-wide investigation of health conditions in Minnesota, has made a report which contains the following specific recommendations, looking toward increased efficiency on the part of the State Board of Health:

1. That it be raised to state department.
2. That all its subdivisions be housed in the same building.
3. An assistant director and two additional bacteriologists for the division of preventable diseases.
4. Division of the state into not less than 20 health districts.
5. Each district to have a physician trained in sanitary science, with an office and adequate assistance, including inspectors, nurses and clerks.
6. Such physician to hold office during good behavior, be paid salary and traveling expenses and forbidden to practice medicine or engage in any business to interfere with his official duties.
7. Such official to have full power to enforce laws and regulations within his jurisdiction, and authority over all county, city and town health officials.
8. His powers and duties to include notifications of cases of disease, inspection of dairies, creameries, etc.; schools and schoolchildren; investigation of nuisances; prevention of disease; registration of births and deaths, and other duties incidental.
9. Field organization to be mobile, so that a force can be concentrated in emergency in any part of the state.
10. Division of sanitation to be increased by five men, four of whom shall have had training in sanitary engineering and one of whom shall be an expert in analysis of water and sewage.
11. Division of state into four sanitary engineering districts.
12. Comprehensive regulations relative to water supplies and the disposal of sewage and refuse.
13. Hereafter all plans of public buildings to be submitted to state board of health as to sanitary arrangements, as required by law.
14. Law to require reporting of all marriages and divorces to state board of health.
15. Tabulating machines for division of vital statistics.
16. That the prevention of occupational diseases and the maintenance of sanitation in places employing labor be controlled by state department of health.
17. Resumption of work relative to school hygiene and child welfare.
18. Provision for distribution of free antitoxin where necessary.
19. Monthly bulletin for use in instructing public schoolchildren.
20. State to pay expenses of district health officers attending annual conference.
21. All officials of department to be full time men.
22. System of cost accounting.
23. More clerks and technical assistants.
24. Minimum appropriation of $270,000 for department of health.

Medicolegal

Physician Not Liable for Taking of Wrong Medicine

(Nicholson vs. Patrick (Ky.), 170 S. W. R. 20)

The Court of Appeals of Kentucky affirms a judgment for the defendant, a practicing physician at a mining camp, who not only prescribed, but compounded his medicines, as there was no drug store or pharmacist in the town. The court says that the defendant prepared for a man, who complained of a stomach trouble, a mixture of nux vomica and May apple root. The mixture was of a brown color and put into a 2-ounce bottle on which the defendant testified that he pasted a label with this written direction: "Take 5 drops in water after each meal." He also gave the directions verbally. A few weeks afterward, the man's wife, suffering from some menstrual disorder, consulted the defendant in his office, and he prepared for her a remedy of brown color, which was put into a 3-ounce bottle, but, without placing any label on the bottle, he told her the dose was a teaspoonful as needed. Then, one morning, after about half the contents of each bottle had been used, she poured out of the bottle which she thought contained her medicine a teaspoonful and swallowed it. Almost immediately, she went into convulsions, but had returned to consciousness by the time that the defendant had reached there. He assumed that she was suffering only from her female trouble, and, no doubt, attributed her marked improvement to the efficacy of his medicine, which she informed him she had taken. With her husband he went to his office and sent back some pills. On returning, the husband gave her another teaspoonful of medicine out of the same bottle from which she had taken the first dose an hour before, which all supposed was the bottle prepared for her a month before, because, as he wanted to testify, the defendant told him to give her another dose of her medicine, and, in about fifteen minutes, the pills. But the medicine again threw her into convulsions, and this time the defendant discovered that she had been taking, by the teaspoonful, the nux vomica and May apple root, the bottle not having any label on it. Whether the defendant did or did not place a label on the bottle of poison was the question on which the case was submitted to the jury, and they returned a verdict for the defendant. Nor was it error that the trial court refused to permit the husband to testify. The question in the case, as it was prepared in the lower court, was whether the bottle was labeled in the first place, and none of the testimony offered by the husband could affect that question, except as to what occurred in the defendant's office when he received the bottle, and, as he got that for himself, his evidence about it was clearly incompetent. It did not come within code exception which provides that when a husband or wife is acting as agent for his or her consort, either of them may testify as to any matter connected with such agency.

Manufacturing of Evidence by Physician a Punishable Offense

(Melton vs. Commonwealth (Ky.), 170 S. W. R. 37)

The Court of Appeals of Kentucky reverses a conviction of criminal contempt, but holds that Melton was, under the evidence for the commonwealth, guilty of the common-law offense of obstructing justice, and for this offense he could have been indicted by the grand jury, and on his trial, if proven guilty, under the rules of law and evidence that obtain in criminal practice; the jury could have assessed his punishment at a fine in any amount or imprisonment for any length of time, or have both so fined and imprisoned him. The information filed charged that one Collins having driven an ice wagon which came into collision with an automobile, certain attorneys endeavored to persuade him that he was injured, when he said he was not, and insisted on his submitting to an examination by the accused, who discovered a small bandage worn by Collins as a result of a slight accident sustained the day previous, and, in spite of Collins' explanation, rebandaged him, saying in substance that "they don't know about that"; also subsequently bandaged him again. It further appeared from the record that the accused did not see or prescribe for Collins in a professional way, or give him any advice, or make to him any suggestions about his injury after suit was brought against the owners of the automobile, by the attorneys. According to Collins' version of the affair, the purpose of Melton was to fraudulently make up a state of facts that would enable him to maintain a suit to recover damages for an injury that he had not sustained. That he (Collins) afterward brought a suit to recover damages was not of controlling importance. The offense of Melton was complete when he attempted, by the methods described, to induce Collins to bring a suit. His purpose was to prostitute the administration of the law and make the courts an instrument of fraud and wrongdoing.

Refusal to Submit to Administration of Anesthetic for Examination

(Chicago, Rock Island & Gulf Railway Co. vs. Pemberton (Tex.), 170 S. W. R. 108)

The Court of Civil Appeals of Texas holds that, after the plaintiff Pemberton had refused to submit to the administration of an anesthetic for the purpose of an examination, there was no error in the court refusing to appoint a committee of disinterested medical experts to examine him for the purpose of testifying as to the extent of his injuries and the probable duration thereof. The court says that while the plaintiff was testifying he pulled up his trousers leg, leaving an openwork drawers leg covering his limb. It was not shown that the outer surface of the knee disclosed any mark indicating the extent of injury, nor was its appearance in any way calculated to arouse the sympathy of the jury. It seemed that the only purpose for raising the trousers leg was that the grating sound made by the working of the knee could be more distinctly heard by the jury and others. No restrictions were placed on the examination other than the refusal to appoint a committee. One of the defendant's physicians had examined the plaintiff just before the trial began and testified in the case. Two of the physicians testified that, in order to make a more thorough examination, it would be necessary to place the plaintiff under an anesthetic. The plaintiff refused to submit to the administration of an anesthetic, and that was the main reason for refusing to appoint the medical committee. The plaintiff's refusal was not unreasonable, and there was no error in the court's ruling.

Care Required of Manufacturers of and Dealers in Food

(Parks et al. vs. G. C. Yost Pie Co. et al. (Kan.), 144 Pac. R. 202)

The Supreme Court of Kansas affirms a judgment for $3,000 damages for the death of a man alleged to have been caused by ptomain poisoning from eating a pie, or a portion thereof, which was manufactured by the defendant pie company and sold by it to a retail grocer who in turn sold and delivered it to the man as suitable food for himself and family. The court says that the degree of care required of a manufacturer or dealer in human food for immediate consumption is much greater by reason of the fearful consequences which may result from what would be slight negligence in manufacturing or selling food for animals. In the latter a higher degree of care should be required than in manufacturing or selling ordinary articles of commerce. A manufacturer or dealer who puts human food on the market for sale or for immediate consumption does so on an implied representation that it is wholesome for human consumption. Practically he must know it is fit, or take the consequences if it proves destructive. The usual rule by which the existence or absence of negligence is to be determined in a particular case is whether the care exercised was commensurate with the danger reasonably to be apprehended.

The Value of Partial Knowledge.—What cannot totally be known ought not to be totally neglected, for the knowledge of a part is better than the ignorance of the whole.—Ismail ibn Ali Abu el Feda (Preface to his Geography).

COLLEGE OF PHYSICIANS OF PHILADELPHIA

Meeting held Nov. 23, 1914

(Concluded from page 81)

Some of the Unusual Features of Tuberculous Meningitis

Dr. Thomas McCrae: The case was one of tuberculous meningitis in which symptoms had existed for eight weeks before death. There was a marked variation in the symptoms, the patient's mental condition changing from day to day. The eye symptoms were also very variable, paralysis being present one day and gone the next. Retraction of the head and Kernig's sign were not particularly marked. Lumbar puncture gave a clear fluid with a cell count of 100. Tubercle bacilli were not found. At necropsy only a few tubercles were found on the cerebral meninges, and there was little change in the meninges themselves. It seemed rather difficult at first to give an explanation of the symptoms when the necropsy findings were studied. The brain was hardened as a whole, and when sectioned three caseous areas were found in the occipital lobes. These contained large numbers of tubercle bacilli. In this case many of the symptoms were apparently due to general toxemia and not to the local tuberculous process in the meninges. The variation in the eye signs seemed most probably to be from edema. The lungs showed a large number of very young miliary tubercles, evidently much younger than those in the meninges. The source of infection was apparently a tuberculous epididymitis.

DISCUSSION

Dr. William M. L. Coplin: The lesions in the gray and white matter of the brain of this case were old, with distinct caseation. It is possible that the extension of infection may have occurred from them to the meninges rather than by hemotogenous dissemination to the meninges, lungs and other organs. I am reminded of one case in which there was perfectly clear evidence of at least two eruptions of miliary tuberculosis. These were seen in the liver in the presence of definitely healed tubercles, and perfectly fresh granulations with absolutely no evidence of any reparative effort.

Dr. Joseph Sailer: I recall a case of tuberculous meningitis in which after one or two years the patient died of some other condition and in which healed tuberculous lesions were found in the meninges.

Dr. B. F. Stahl: In a case reported some time ago, the patient had tubercle bacilli in the spinal fluid, had all the symptoms of meningitis and in addition had tuberculosis of the lungs; and, if I remember clearly, he had a cavity. The patient made a surprising recovery from his tuberculous meningitis. I saw the patient four years afterward, and the disease was entirely arrested.

Dr. David Riesman: A woman, stout and healthy looking, presented continuous fever with intense headache. There was history of two separate attacks of typhoid. There was no positive Kernig's sign, but some rigidity of the neck. Lumbar puncture showed the spinal fluid to be almost typical of tuberculosis. Complete recovery took place. I recall the cases of two middle aged women who seemed to have typhoid fever. In the examination of one a little lump was discovered in the back, probably the result of an old Pott's disease. Subsequently all the symptoms of miliary tuberculosis developed and the patient died of that disease. In the second patient the picture was definitely that of typhoid. She had also a little enlargement in the back. This together with the headache suggested tuberculous meningitis, which the condition was subsequently proved to be. I feel, therefore, that these small lesions in the intestines, epididymis and in the joints are not infrequently the cause of a miliary tuberculosis or tuberculous meningitis. I would particularly point out that these little remnants of an old and forgotten Pott's disease are very interesting in diagnosis.

Dr. Robert L. Pitfield: In a case of meningitis, lumbar puncture showed tubercle bacilli, diplococci and pneumococci.

The edema of the face, choked disk and the fact that the complete coma was not relieved by lumbar puncture led me to think that possibly the cause of the comatose condition was a blocking up of the foramen of Monro and the overflow of fluid into the left ventricle. Dr. McCrae's case might be due to an accumulation of fluid as well as to the toxic condition mentioned.

Dr. A. P. Francine: I have seen three cases which developed many of the typical features of meningitis which remained for a definite period, and in which a diagnosis was made of tuberculous meningitis in the course of advanced pulmonary tuberculosis. All three cases cleared up without evidence of tuberculous involvement of the meninges or brain. I therefore look on these cases as possibly of nephritic origin or due to toxemia. I am rather skeptical of a tuberculous meningitis with recovery. I have seen recovery in such so-called cases, but there has been a complete absence of tuberculous meningitis.

Dr. Alfred Stengel: I recall a woman with marked cerebral symptoms who soon developed a paralysis of the external rectus muscle in one eye with marked diplopia. There was retinitis with swelling of the nerve head. There were somnolence and various other nervous disturbances not terminating in coma. The condition had begun with apparently acute infection which we eventually discovered to be tuberculous. While tuberculous meningitis was not demonstrated, its suggestion was very strong and it might possibly have been a case of healed tuberculous meningitis. Another case was one in which there were all the symptoms of tuberculous meningitis in a young boy who had tubercles in the retina. There was complete recovery from the meningeal and retinal conditions. These two cases suggest the possibility of healed tuberculous lesions in the meninges.

I believe with Dr. McCrae that in tuberculous meningitis the symptoms are due, not to the local tuberculous process, but to the associated toxemia and perhaps to the vascular changes as well. Were the cerebral symptoms due to previously established organic lesions, the extraordinary changeability in these symptoms from day to day could hardly take place.

PHILADELPHIA COUNTY MEDICAL SOCIETY

Meeting held Dec. 9, 1914

The President, Dr. William Duffield Robinson, in the Chair

SYMPOSIUM ON RETRODISPLACEMENT OF UTERUS

Gilliam Operation for Deviations of Uterus

Dr. D. Tod Gilliam, Columbus, Ohio: My operation is the pioneer ventrosuspension of the uterus by means of the round ligaments *in which the ligaments are left intact in their natural investments.* The many modifications of the original operation emphasize the value of its principle. The following is a description of the operation as I do it to-day: 1. An abdominal incision 3 or 4 inches in length is made in the median line at the usual site between the umbilicus and pubes. 2. The adhesions are broken up and the fundus brought forward. 3. By lifting up the broad ligament of one side on the tip of a finger applied to the posterior surface, the round ligament is brought into view and is picked up by a bullet forceps. 4. Selecting a point 1½ inches from the uterus, a thread is passed under the round ligament and the ends of the thread are brought out of the opening and secured in the bite of a clamp forceps which is laid on the surface of the abdomen. 5. The other ligament is sought for and secured in the same manner. 6. At a point about 1½ inches above the pubes, the peritoneum, muscle and fascia are caught up by a volsella and pinned together, care being taken that the edges of these layers are approximately in line. 7. Traction is now made, and with a claw retractor the skin and superficial fat are drawn in the opposite direction, and by a sweep of the knife the face of the fascia is laid bare. 8. With a Cleveland ligature carrier or some similiar instrument a stab wound is made from the surface of the fascia into the peritoneal cavity, 1 inch from the edge of the abdominal incision. The jaws are separated and by an outward movement of the handle brought into plain view at the large opening. The thread which loops the round ligament is now placed in the jaws, the clamp forceps removed and the ligature carrier withdrawn, bringing with it the thread and the ligament. 9. While the ligament is held taut, with its loop end just above the surface of the fascia, a catgut suture is passed through it, including the tissues on either side, then back again where it is tied. This is cut close to the knot, and the suspending thread removed, perferably by clipping it close to where it passes under the ligament, to avoid possible contamination. 10. The volsella and retractor being removed, the other side is dealt with in like manner and the incision closed.

After both ligaments have been fastened, the conditions are such that strangulation of the bowel is scarcely conceivable. The uterus rests easily and naturally on the bladder, from which it can be raised to a position a little short of vertical. So far as I know there has not been a single instance in which pregnancy or parturition has been embarrassed, and there have been no untoward results of any kind. In a few isolated cases in which it was averred that intestinal obstruction occurred, the condition should not be credited to the operation per se. The majority of the failures have been due to insecure attachment to the abdominal walls.

Operative Treatment of Retroversion of Uterus

Dr. Edwin B. Cragin, New York: In June, 1905, I turned to the principle of the Gilliam operation of shortening the round ligament. After performing two or three of these operations through a median incision, I adopted the Pfannenstiel incision because, among other reasons, of its simplicity of technic, the safety of the cicatrix and the cosmetic result. Because of an unsatisfactory anatomic result in one case, I have been careful since November, 1905, to perform the operation so that the loop of round ligament when sutured lies just beneath the fascia and does not perforate it. Since then I have had no further trouble with sloughing of the ligament. Any operation for retroversion of the uterus, to be called satisfactory, must be (1) safe, (2) permanent in its results, and, (3) must not interfere with pregnancy, parturition or the puerperium. Of 400 operations during the nine years ending last June, I lost one. This was a complicated case in which nothing but an intra-abdominal operation would have met the indications. In the series of 400 operations, there were 127 complicated cases.

Regarding permanence in results, in 164 cases heard from in the series of 400, and calling a uterus which lies in the axis of the vagina a partial anatomic failure, I have two partial anatomic failures, two complete anatomic failures, and two symptomatic failures, although anatomic successes. Among these 164 cases, pregnancy has occurred in 35, and without marked discomfort. Of the 35 women who became pregnant after the operation, 22 went to term and bore a living child; 1 has had two living children since the operation; 9 are now in the course of pregnancy, and 4 have had miscarriages induced or natural. Of these 4, 1 has had seven induced abortions since my operation; 1 has had two. One miscarried after a fall, and one had a miscarriage without assignable cause, but she had one living child before this miscarriage and since my operation, and is now advanced about four months in her third pregnancy. This gives one miscarriage after and one miscarriage without assignable cause in thirty-eight pregnancies, which does not seem a greater frequency than one would expect in women not operated on. One of these women became pregnant at once after leaving the hospital; another menstruated only once before becoming pregnant. In none of the patients who went to term have I been able to get any history of dystocia. The involution of the uterus has been normal. The absence of hernia in any of the cases heard from suggests that leaving the opening in the rectus just large enough for the round ligament loop makes the occurrence of hernia very improbable.

Surgical Treatment of Retroversion of Uterus with Special Reference to the Lower Pole

DR. J. WESLEY BOVÉE, Washington, D. C.: To select the proper corrective operation intelligently, an understanding of the forces maintaining the uterus in what may be called its normal position is essential. It hardly seems proper to rely entirely on shortening the round ligaments to correct retroversion of the uterus. I believe success will attend this procedure only when a strong ligament exists or is strengthened by plication and markedly shortening it. My views regarding operations for retroversion of the uterus are, briefly, as follows: 1. Round ligament shortening, per se, does not usually contain all required elements in the treatment of retroversion of the uterus, though it may end the displacement. 2. No single operation devised is more successful than is it. 3. The displacement is more certainly influenced by the ligamentation at the lower pole than by other forces, and, therefore, the proper adjustment of these forces is of paramount importance. 4. Without predilection for any particular operation, the exact cause or causes of the displacement must be sought and the indicated operation performed. 5. The vaginal route alone is not applicable, except in the roomy vagina of the multipara, or when the operation is limited to the anterior vaginal wall and broad ligament bases. 6. The round ligament shortening is often advisable as an adjunct to operation on the ligaments at the lower pole of the uterus.

Operative Treatment of Retrodisplacements of Uterus

DR. E. E. MONTGOMERY, Philadelphia: Modifying the Gilliam operation, a loop of round ligament has a ligature passed around it, the ends of which are threaded into a Deschamps needle. The ligament is seized with hemostats external to the point about which the ligature is thrown around it, an opening is made in the anterior surface of the broad ligament, and through this opening the needle carrying the suture is passed until it reaches the point where the peritoneum is reflected on to the anterior abdominal wall. Hugging the peritoneum, it is pushed through and brought out on the aponeurosis, unthreaded, and the ends of the loop secured with hemostats. A similar course is followed on the other ligaments. Holding the ends of the ligature tense, a pair of sharp pointed scissors closed are inserted along the ligature, slightly separated, when traction generally results in pulling the loop through. The fatty tissue is pushed back, exposing the aponeurosis of this loop, secured by chromic catgut sutures on either side, taking up the approximal and distal ends of the loop. I first performed this operation June 11, 1904, and have had in all 756 cases. In nearly all of these cases this operation has been a link in a chain of operations designed to correct various pathologic conditions associated with displacement. The principal operations in their order of frequency have been curettement, 632; appendectomy, 507; perineorrhaphy, 239; trachelorrhaphy, 175; amputation of cervix, 104; resection of ovary, 58, and anterior colporrhaphy, 56. I have had five deaths, all of which occurred prior to 1909. The last 400 cases have been without mortality.

The advantages of the operation are: 1. It is easily accomplished. 2. It leaves no injured surfaces to favor adhesions. 3. It affords support by structures capable of evolution and involution, and consequently, well calculated to stand the test of subsequent gestation.

Principles and Practice in the Surgical Treatment of Retrodisplacements of the Uterus

DR. J. CLARENCE WEBSTER, Chicago: I have endeavored to carry out certain principles: 1. The operation should restore the soft parts of the pelvis as nearly as possible to normal. 2. In the child-bearing period the operation should not introduce any factor which interferes with the safety of pregnancy and labor. 3. It should also be of such a character as to make it possible for the woman to bear children with the reasonable hope that there shall be no recurrence of the displacement. 4. The operation must be carried out so as to make thorough exploration of the pelvic cavity possible, so that all associated pathologic conditions may be dealt with. The technic employed must not cause such trauma as will give rise to after-trouble.

The anatomic relations of the uterus should constantly be borne in mind. I have long since abandoned all operative procedures carried out through a vaginal incision, such as shortening of the round or uterosacral ligaments, or vaginal or vesical fixation; also all procedures carried out by the abdominal route resulting in the slinging of the uterus from the abdominal wall by an artificial band, or in the pulling of the fundus toward the parietes by the shortening of the round ligaments. A damaged pelvic floor must always be repaired. This is the largest contributing factor to success. The abdomen should be opened by the suprapubic mesial incision, when the procedure is determined by existing conditions. In a typical uncomplicated case, I first carry out what is termed "shortening of the uterosacral ligaments," but what is really the making of new ligaments out of the peritoneum and subjacent tissue. I always use linen sutures in making these ligaments, to ensure development of fibrous tissue.

I then cause the fundus of the uterus to be directed forward to the pubes in its normal position, by shortening the round ligaments and stitching them securely to the upper part of the posterior surface of the uterus. The broad ligament is perforated with a curved forceps immediately under the utero-ovarian ligament close to the uterus. Emerging just above or behind the round ligament an inch or more (according to the length of the stretched ligament) from its uterine end, the forceps grasps the ligament and pulls it through the opening, doubling it on the back of the uterus. This bent portion is spread out as widely as possible, the smooth peritoneal surface being uppermost (superficial). The under surface is then stitched to the uterus with linen suture. The latter is completely buried under the ligament, the edges of which are stitched to the uterus with catgut. The other round ligament is then similarly dealt with.

The next stage is important—the closing of the openings in the broad ligaments, stitching their edges to the round ligaments. When the uterus is large, the level of the utero-ovarian ligament abnormally low, or the outer ends of the round ligaments much thinned, I stitch the round ligaments with linen to the edge of the uterus immediately in front of and above the opening made in the broad ligament. When the operation is accompanied by the removal of a tube or tube and ovary on one side, the round ligament is shortened on this side by doubling it back directly without perforating the broad ligament, care being taken to cover all raw surfaces. In bilateral removal this is done on both sides. In the after-care, all forms of strain on the stitched parts must be avoided for several months. Pregnancy should not be allowed to commence until a year has elapsed, and then it is advisable that a vaginal pessary should be worn during the first three months. After the eighth week of the puerperium it is a wise precaution to use a Hodge or Albert Smith pessary for several months.

Modification of the Alexander Operation

DR. BARTON COOKE HIRST, Philadelphia: I still believe in the treatment of retroversion of the uterus. When a woman comes to me with the train of symptoms attending this condition, and I cure her retroflexion, at the same time giving her symptomatic relief, I feel that I have done her some good. Only within the last two years, however, have I felt satisfied with my operative method. I submit that the ideal operation for retroversion of the uterus is (1) one that will restore the uterus to its natural position; (2) give the patient symptomatic relief; (3) withstand the strain of subsequent pregnancies; (4) does not complicate subsequent pregnancies or labor; (5) and causes no subsequent complications such as obstruction of the bowels. Conditions one and two are met by shortening of the round ligaments. Regarding the third requirement, in over twenty years' experience, the Alexander operation has given the smallest number of recurrences; and, what is particularly important, among the few failures, not one, to my knowledge, has followed subsequent child-bearing. In one case there were five childbirths; in another case four, and not one patient has yet reported complications. The Pfannenstiel operation also obviates the defect of overlooking intra-abdominal complications. The detailed technic of the operation is best described by reference to a series of illustrations. The withdrawal of the round ligament for a sufficient length is a point on which many surgeons go astray. A single stitch of No. 3 catgut is used temporarily to suspend the uterus and to take the strain off the round ligaments. Incision of the peritoneum exposes to view the abdominal organs. The uterus is seized by a Summers' clamp, which is a convenient instrument. Closure of the peritoneal incision occupies only a few minutes. Then the round ligaments are fastened by a series of sutures to Poupart's ligament. The fascia is united and the skin is closed as in an ordinary abdominal section.

Discussion on Retrodisplacement of Uterus

Dr. J. M. Baldy, Philadelphia: The details of the operation bearing my name have been given in the main in the paper by Dr. Webster. As a matter of historic interest, great injustice has been done Andrews of Chicago, who did practically this operation a year prior to the work of Dr. Webster and myself. If retrodisplacement causes the symptoms for which we operate, then any operation that will replace the uterus will cure those symptoms. The trouble is that too much prominence is given to retrodisplacements, and patients are operated on who ought never to be touched for retrodisplacement. Instead of bothering ourselves about what each one is doing perfectly, we should replace the uterus, if that is causing symptoms, and keep it replaced by any satisfactory method that will cure the symptoms. As a matter of fact, in nine out of ten cases the symptoms do not come from it at all. It is the complications that are causing the symptoms.

Dr. Howard A. Kelly, Baltimore: The history of retrodisplacements of the uterus may be divided into four periods:

1. The Ancients down to about the year 1600. Prolapse was recognized, but otherwise little was known of displacements which were confused with wanderings of the uterus into various other parts of the body and various imaginary conditions, such as dryness, softness, distortion and compression.

2. From 1600 to about 1810. During these years there was an increasingly clear recognition of the extreme danger of retroflexion of the pregnant uterus. William Hunter, in 1774, reports a case treated by emptying the bladder, putting the patient in the knee-chest posture, and endeavoring to replace the uterus by using the fingers of one hand in the rectum, pushing in the sac, and those of the other hand in the vagina manipulating the cervix. The patient died and a post-mortem showed that the womb was so tightly wedged in the pelvis that the symphysis had to be divided to get it out. During this period the method of examination was the introduction of a finger into the vagina, technically called the "touch." Retroflexion apart from pregnancy had to be defined as "retroflexion in vacuity." The first case reported in this country was by Dr. Holyoke of Salem, Mass., in 1806.

3. From 1810 to 1885. It now became increasingly evident that retrodisplacements were common. Sir James Y. Simpson almost felt as if he had discovered them with his uterine sound. A number of works in this period were devoted to the subject, among which I would mention especially that of Laroux, published in 1844. This may be called the pessary period of gynecology, when great reputations were made by the invention of a new pessary, and when pessaries were patented and even hawked from door to door.

4. The last, or operative period. This began in the eighties of the last century, when the profession finally broke away from the dominion of the pessary and brought retroflexion operations into the category of other gynecologic procedures which were rapidly becoming almost exclusively surgical. Since that date the pessary has occupied a very subordinate place.

As to the frequency of retroflexions, at the Johns Hopkins Hospital out of 13,600 gynecologic cases, there were 1,886 of retroflexion. Of these, 415 were uncomplicated. Of 1,000 operations of all kinds performed there between Aug. 27, 1904, and Nov. 9, 1905, there were ninety-five cases of retroflexion. My own operation, which was done in 1885 and published January, 1887 (*Am. Jour. Obst.*, xx, 33), I have abandoned after doing it between 700 and 800 times; on account of the occasional accidents or a difficult birth. I now use an operation by which a single silk or linen thread on either side encircles the round ligament and draws it forward to the abdominal wall, where these are tied to the deep fascia over the rectus muscles. The peritoneum between the abdominal wall and the ligament must be picked up at every half inch, in order not to leave a hole for the bowel to slip through. I have done this eighty times and believe it will prove to be the most satisfactory operation yet devised.

Dr. John G. Clark, Philadelphia: The point made by several of the speakers, that the retrodisplacement many times causes no symptoms, is one of the strongest arguments for any operation that gives a liberal insight into the abdominal cavity, so that all complicating conditions may be corrected.

3. **Placental Proteins in Skin Reactions.**—Falls and Bartlett found that proteins prepared from the placenta in this way, or whole placenta when introduced by the von Pirquet intracutaneous or subcutaneous method, do in most cases cause a local reaction in pregnant and non-pregnant individuals. The difference in the reaction, however, is neither great nor constant enough to be of value in the diagnosis of pregnancy. This the authors claim speaks against the theory that the pregnant woman is specifically sensitized to placental proteins. The lack of a general anaphylactic reaction also speaks against the view that the pregnant woman is in fact a sensitized woman.

4. **Experiments on Etiology of Eclampsia.**—Hull and Rohdenburg are of the opinion that eclampsia develops in the following sequence: An overload of fetal elements is thrown into the circulation and, whether in the circulation or not, is autolyzed with the formation of an excess of leucin. The excess of leucin injures the hepatic vessels with consequent thrombosis, cloudy swelling, local necrosis, and more or less complete autolysis of the liver cells. The renal changes are probably due in part to other products of autolysis, and, perhaps, also the protein fractions incompletely broken down by the liver. The surprising feature of the process is the extent to which the liver may be damaged experimentally before clinical symptoms appear in the animals. Judging from analogy, such may well be the case in the human subject. The hemorrhages and the convulsions

Hull and Rohdenburg believe to be due not to extensive hepatic changes, but to the renal lesions. It appears from Hull and Rohdenburg's experiments that albuminuria is an important sign, since severe renal degeneration seems to be the important lesion. The urines of the experimental animals contained enormous quantities of albumin and all varieties of casts, even though there were but slight gross and microscopic changes in some of the kidneys. The experiments further suggest that a negative protective ferment in a known pregnant female and a determination of the leucin content of the blood will prove to be diagnostic procedures of value. The authors suggest that it is possible that a negative reaction so frequently noted in eclampsia, both in man and animals, is due to the inhibition of the activity of the ferments by an excess of their own products.

12. **Plastic Operation for Correction of Ceco-Colon Stasis.** The operation devised and employed successfully in three cases by Marvel aims to elevate the cecum and reduce the retention capacity of the ascending colon. It restricts the caliber of the colon and eliminates the cecal pouch. This is accomplished by approximating two of the three longitudinal fibrous bands which enter into the formation of the colon wall in such manner as to invaginate that part of the bowel lying between. The appendix having been removed and the stump invaginated and covered, the most dependent point in the anterior fibrous band is caught by a Lembert suture of non-absorbable thread, which suture is carried sufficiently high for its attachment in the external band that when tightened the bottom of the cecum is brought to a level with the ileocecal juncture. Sufficient interrupted Lembert sutures are then placed to completely approximate these two bands in line of their course from their origin at the base of the appendix to the site of the first suture. Additional sutures of the same type are placed above the first suture to the point in which the caliber of the colon ceases to be dilated or to the hepatic flexure. A continuous suture is then placed bringing the serosa over the interrupted suture, thereby reinforcing the approximation by an additional line of union.

13. **Longitudinal Inversion of Colon.**—In redundant sigmoid cases after making anastomosis for short-circuiting, instead of cutting out superfluous sigmoid, Morris attempted to lessen the degree of traumatism by painting this bowel longitudinally with iodin, and then running a suture in such a way that when it was drawn it would bury the painted part longitudinally. This transformed the redundant part into a narrow "rope," and dependence was placed on the iodin for causing strong adhesion. The idea is to do away with the severity of the operation of colectomy.

19 *Present Status of Crotalin in Treatment of Epilepsy. D. A. Thom, Palmer.

19. **Present Status of Crotalin in Treatment of Epilepsy.**—After selecting 203 cases free from any clinical evidence of organic brain lesions, Thom began to study the coagulability of the blood in epileptics. Blood was taken for this purpose before, during and after convulsions; 92 per cent. of these cases fell within normal limits, 5.5 per cent. was less than the minimum limit, and 2.5 per cent. over the maximum limit. Thom became convinced there was no relation between the coagulation time of the blood and convulsions in epileptics. Fourteen cases of idiopathic epilepsy were started on crotalin with the intention of continuing for three months. On three of these patients it was necessary to suspend treatment; in the first case because of the development of hysteric attacks; in the second the convulsions were so markedly increased in frequency and severity that at the patient's request treatment ceased; the third case exhibited such violent local and systemic reactions that Thom did not feel justified in continuing the injections. Of the remaining eleven cases which were kept on treatment for the three months, six became worse, that is, the convulsions were either increased in frequency and severity or some unusual mental disturbance made itself manifest; four showed no change whatsoever; and one, a typical case of hysteroepilepsy, showed improvement, undoubtedly the psychologic effect of the administration rather than the drug being the cause. From Pennsylvania, Virginia and Michigan, with his own personal work, Thom gathered fifty-eight cases. Six, or less than 10 per cent., showed improvement; twenty, or more than 35 per cent., became worse, and three died while treatment was being carried out. The remaining twenty-nine cases were apparently unaffected by the drug.

33 Tuberculosis of Spleen. J. Halpenny, Winnipeg.

30. **Complement-Fixation Test in Gonorrhea.**—Tests were made by Ower on 375 human sera, in 218 of which the presence of a gonorrheal infection was known or suspected. Six strains of gonococcus were used in the polyvalent antigen. The results were as follows: Acute urethritis with symptoms present for ten days or less, and with gonococci in smears, 21 cases, all negative. Acute urethritis of three to six weeks' duration, 17 cases, 9 weakly positive, 8 negative. Chronic urethritis of over six weeks' duration, 22 cases, 13 positive, 9 negative. Epididymitis: (a) 19 cases with definite history of urethritis; 15 positive, 4 negative. (b) Four cases with no history of urethritis, all negative. Two were operated on later and found to be tuberculosis. One gave a positive Wassermann reaction.

Prostatovesiculitis, 40 cases, the majority of which were chronic and resisting treatment; 22 positive, 18 negative. Arthritis: (a) Acute, with no history of urethritis and clinically of type of acute rheumatic fever; 10 cases, all negative. (b) Acute with history of recent urethritis; 8 cases, all positive. (c) Chronic: Eight cases (female), clinically gonorrheal arthritis; 6 positive, 2 negative. Eleven cases, with no definite history or indication of gonorrhea; 3 positive, 8 negative. Colliculitis; diagnosed by urethroscopic examination; 7 cases, all negative. Stricture: 3 cases, all negative. These cases had not had symptoms of gonorrhea for over ten years previously. Conjunctivitis: 1 case of acute conjunctivitis of the right eye showing gonococci in smears, gave a positive reaction. Salpingitis; 23 cases, showing symptoms of acute or chronic inflammation of the fallopian tubes; 14 positive, 9 negative. Of these negative cases, 4 at operation were found to be tuberculous; 1 showed both tubercle bacilli and gonococci in smear, and a culture of the latter was obtained.

In addition to the above, serums were examined from eight cases in which gonococcus vaccine had been administered. These all gave positive reactions. In 130 serums the tests were performed, using both a monovalent and a hexavalent antigen. The latter was found to give on the whole distinctly better results. With it four cases were positive which were negative with the monovalent antigen. In those serums in which both antigens gave positive reactions, the hexavalent gave almost without exception the stronger reaction. An analysis of the cases seems to show that the best results are obtained in cases in which the lesions occupy sites in which there is possibly a lack of free drainage.

31. **New Method of Reducing Dislocation of Big Toe.**—Chisholm's method is to cut the extensor of the toe, then to hyperflex it, and pull it while in this position. In this maneuver the first phalanx acts as a pry with the head of the metacarpal bone as a fulcrum. The pry disengages the heads of the flexor brevis pollicis, the abductor and adductor pollicis, the long flexor tendon and the capsule. When this is done a slight pull in the hyperflexed position and direction makes the phalanx slip into position over the head of the metacarpal bone, carrying all the displaced structures with it. Suture the divided tendon and close the flap raised in exposing it.

52 *Diagnosis and Surgical Treatment of Goiter. G. Link, Indianapolis.

52. **Diagnosis and Surgical Treatment of Goiter.**—Link's experience in thyroid surgery covers twenty-seven operations done on twenty-one patients. These patients all suffered from thyrotoxicosis except two. Of these twenty-seven operations, one patient died following the operation, a thyroidectomy. There were eighteen thyroidectomies with one death; the other seventeen are living. Two patients on whom ligations had been done merely to alleviate their condition, died; one a year later, one six months later. Both of these were recognized as incurable on account of the extent of cardiac disability, and thyroidectomy was never attempted. Ligation in each case gave relief and benefit, justifying the work. All patients report marked improvement and most of the patients consider themselves cured. One patient who submitted to double polar ligation (March, 1911) now has a normal pulse, and thinks herself well. The technic employed was that used in the Mayo clinic, with modifications suggested by Wathen. Ether anesthesia has been used in most of the thyroidectomies, gas-oxygen in four cases satisfactorily, and local anesthesia once. The method of performing the operation without the patient's knowledge has been used twice.

60. **Tick Paralysis.**—Previous publications have proved: (a) That a paralysis in children may be associated with the bites of ticks in western North America and Australia. (b) That a paralysis of sheep has been associated with the bites of ticks in British Columbia and in South Africa. (c) That the ticks associated with these affections are of more than one sort. (d) The *Dermacentor venustus* has produced paralysis in lambs and in a puppy in experiments made under laboratory conditions. (e) That the paralysis following tick-bite is probably an individual and novel condition. The paralysis of children is not infrequently accompanied by elevation of temperature and by other constitutional symptoms; it is possible that symptoms resembling those observed in children sometimes may appear in adults who have been bitten by ticks.

Todd found that under experimental conditions by no means every tick-bite produces paralysis in laboratory animals and that a weak extract of ticks will not cause paralysis when injected into white rats, even though it possesses definite power to prevent the coagulation of blood. The symptoms of these cases suggest infantile paralysis (acute poliomyelitis) but they are probably to be distinguished from cases of that disease by the invariably transitory nature of their paralyses. In no instance has "tick paralysis" left permanent disability.

62. **New Malaria Plasmodia.**—The reasons underlying the production of morphologically atypical generations of malaria plasmodia are obscure, but Craig is convinced that insufficient dosage with quinin, and perhaps with other drugs, often leads to the production of such plasmodia and that these plasmodia may retain for several generations morphologic abnormalities produced by adverse agencies, either physical or chemical. He has followed infections in which the plasmodia were very atypical, being modified morphologically by the exhibition of small doses of quinin, and has seen a return to normal morphology when the drug was discontinued. One of the most common effects of quinin is a great stimulation in the ameboid activity of the malaria plasmodia and an apparent stimulation in the division of the chromatin, as evidenced by the presence of delicate pseudopodia containing an abnormal amount of chromatin during the early stages of development of the plasmodia.

Craig is satisfied that *Plasmodium tenue* is an atypical form of *Plasmodium vivax*. He has observed identical forms, so far as can be judged from the description and drawing, not once, but a considerable number of times, in supposedly untreated infections with *Plasmodium vivax*, and many times in infections with this plasmodium after the exhibition of doses of quinin insufficient to kill the plasmodia. Whether or not this parasite is identical with *Plasmodium vivax*, it cannot be accepted as a new species until the morphology of the parasites during the entire human life cycle at least is studied, for the only claim it now has to specific rank is the resence of slight differences in morphology during a very imited portion of the human life cycle; that is, the early npigmented stages of development when such differences e commonly observed even in the well-recognized species of plasmodia.

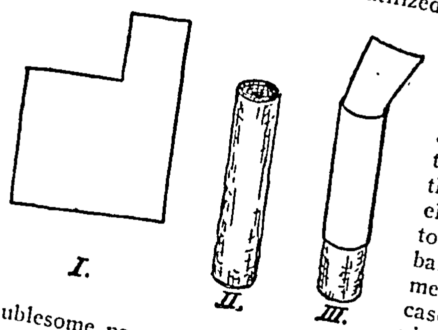
98 *Therapy of Fever in Pulmonary Tuberculosis. E. N. Packard, Jr., Saranac Lake.

91. **New Method for Control of Postanesthetic Nausea.**—eing convinced that the prime factor in this nausea and vomiting is the smell of the anesthetic, Lumbard succeeded in controlling the nausea and vomiting by substituting some pleasant odor for the offensive smell. This he accomplished by the following method:

A piece of adhesive plaster is cut to the shape shown in *I.* in the accompanying figure. Then a piece of gauze is made into a roll of eight or ten thicknesses, about 2 inches long and ½ inch wide, as shown in *II.* Now the adhesive plaster is folded over the gauze roll, leaving a small end of plaster free to fasten to the nose, as shown in *III.* This appliance is fastened to the nose so that the free end of the gauze extends a short distance beyond the tip of the nose. On the end projecting beyond the nose is dropped a little perfume. A mustache may be utilized instead of gauze. The author's choice is oil of bitter orange peel. This perfume should be applied immediately after the anesthetic is withdrawn, the head being then elevated and turned to one side. Lumbard has tested this method in many cases, in which previous anesthesias had produced very troublesome nausea and vomiting with perfect success.



96. **Ehrlich's Aldehyd Reaction for Urobilin.**—The urines of twelve men were used by Berkowitz for this series of tests and three to four specimens in each instance, making a total of about forty analyses. In each urine a deep red color appeared as soon as the reagent was added, showing what would be considered a heavy urobilin reaction. In a series of 500 urine analyses of 214 patients with the aldehyd reagent performed independently of the clinical, operative, or post-mortem diagnosis, in a group of twenty-five patients whose urines were examined seventy-five times, only forty-eight reactions were positive. These patients represented medical, surgical and gynecologic ailments. In a majority of the cases the other chemical and the microscopic analyses were negative. In many instances there were no diseases which could be explained by any of the theories as the etiologic factor for the urobilinuria. The confusion that occurs in trying to arrive at any logical conclusions, Berkowitz states, limits the value of Ehrlich's aldehyd.

98. **Therapy of Fever in Pulmonary Tuberculosis.**—The points emphasized by Packard in the therapy of fever in tuberculosis are: First and foremost, absolute rest in bed, preferably out of doors; artificial pneumothorax in selected cases; a trial with autogenous vaccines, especially when there is copious purulent expectoration; the cautious use, if at all, of tuberculin, and then only after other measures have failed; hydrotherapeutic measures suited to the condition and comfort of the patient; and ample diet, but not necessarily "forced feeding;" and the judicious use of medicinal antipyretics.

106. **Drainage in General Peritonitis.**—The method Leighton has employed consists in opening the abdominal cavity at the site of the focus of infection, treating the lesion as

indicated by the condition found with as little and as gentle handling of the peritoneum as possible, then inserting large cigarette drains to the pelvis, right inguinal region and right flank. The wound is closed rather loosely so as not to constrict the drains, as drainage and not the prevention of hernia is the aim sought. The patient is then placed in bed, without elevation of the head, in the ventral decubitus. The method has proven very successful. The drainage has been free and abundant for the first few days. The effect on the temperature has been striking. In several cases practically dropping to normal on the second day. In a series of nine cases of diffuse peritonitis, Leighton has had eight recoveries and one death, and in seven cases of local peritonitis there were no complications.

127 Treatment of Chronic Leg Ulcers. H. D. Sonnenschein, New York.

123. **Phenolsulphonephthalein Renal Function Test.**—When making up the 1,000 c.c. standard 100 per cent. phenolsulphonephthalein solution, Fanz adds a quantity of the patient's urine, obtained just before injecting the indicator, equal in amount to the first hour's urinary output after the injection. The standard solution now will have approximately the same amount of urinary salts as the specimen solution, and the standard and urinary solution will equal each other in opaqueness and yellowish tint, making color comparison easy. To make up the standard solution, he uses 1 c.c. of the contents of an ampoule of the phenolsulphonephthalein, adds the patient's urine (obtained before injecting the indicator) in amount to equal the first hour's urinary output after appearance of the drug. Alkalinize this mixture with 25 c.c. of 10 per cent. potassium hydroxid, filter, and add sufficient distilled water to make up 1,000 c.c. This is the standard and contains 100 per cent. of the indicator in 1,000 c.c.

The first hour's urinary output after injection of the 2 c.c. phenolsulphonephthalein is now alkalinized with 25 c.c. of the 10 per cent. potassium hydroxid and filtered. To this is added enough distilled water to make 1,000 c.c. This is the test specimen. By diluting a unit of the standard, say 50 to 100 or 200 c.c. with distilled water until it matches the 1,000 c.c. solution of the first hour's urinary output the direct percentage of the indicator in the first hour's specimen can easily be estimated. Say, 100 c.c. of the standard had to be diluted up to 500 c.c. before it matched the first hour's specimen dilution, then the standard would be five times as strong as the specimen, or the specimen would contain 20 per cent. of phenolsuphonephthalein. The second hour's output of indicator (phenolsulphonephthalein) is estimated precisely like the first.

139. **Cancer of Pyloric End of Stomach.**—Twelve operations have been done recently in the Mayo clinic by Pólya's method with one death from pulmonary embolus, the necropsy showing perfect condition of the operative field. The technic employed is as follows: The diseased portion of the stomach is removed in the usual way and the stump of the duodenum closed and buried. An opening is made in the avascular arcade of the transverse mesocolon and the upper jejunum pulled through until it can be easily brought into contact with the stomach. The end of the stomach which is held in the crushing clamp of Payr, is united by suture to the loop of jejunum quite as the ordinary gastroenterostomy is made. If the diameter of the end of the stomach be very large, it can easily be diminished by placing

the sutures in such manner as to take a proportionately greater bite in the stomach than in the intestine, thus reducing the lumen of the stomach as the suturing progresses. The stomach is anastomosed to the jejunum at a point in which the jejunal blood supply is extraordinarily good, and the jejunum can be depended on to do more than its share in the healing process. Before the inner through-and-through sutures are placed, the stomach and intestine are grasped with elastic holding clamps to prevent soiling, the inner row of sutures is then run entirely around and the outer row completed. The entire anastomosed end of the stomach is then drawn down below the transverse mesocolon and the margins of the opening in the transverse mesocolon carefully attached by a number of sutures to the wall of the stomach. Fine silk is used for the peritonemuscular sutures and chromic catgut for the through-and-through inner row.

140. **"Lavandera's Ankle."**—In Manila Davis found a bursitis which he terms "lavendera's ankle." Many of the washerwomen, or lavanderas, do their washing in the rivers; and generally a flat rock which is close to the surface of the water and well down in the river is selected. The position assumed when working is such that the lateral aspect of the leg is next to the rock, the external malleolus thus coming forcibly in contact with the hard surface. The weight of the opposite leg rests on the median aspect of the leg next the rock. And thus with the to-and-fro scrubbing movements a considerable pressure is applied over the prominence of the external malleolus. Histologically, the walls of the bursa are found thickened, and the pathologic process may be classified as chronic fibroid or proliferative bursitis.

142. **Two Cases of Filariasis.**—The clinical manifestations of the two cases reported by Armstrong and Mullally were similar. The outstanding feature of interest in the pathologic findings was the presence in each case of a huge lymphatic varix, extending from the groin into the thorax, unassociated with a chylous exudate.

147. **Syndesmorrhaphy and Syndesmoplasty.**—An operative condition of the ligaments in Phillips' opinion exists in frank injuries in which there is reasonable grounds for suspecting a completely ruptured ligament; in old sprains in which after the lapse of one or two months there is still distinct abnormal mobility; in cases of recurring sprains leading to frequent disabilities; in compound sprains or in compound dislocations.

148. **Phenolsulphonephthalein Test.**—Tracy does not believe it to be possible to work out the minimum percentage phenolsulphonephthalein output which will be safe to undertake surgical operations, nor is it possible from the phenolsulphonephthalein test to determine what cases should or should not be subjected to operation. He believes it will never be possible to determine this point by any laboratory test, as the functional activity of a kidney varies under numerous circumstances and at different times. In determining whether or not a patient should be subjected to operation, the history, clinical symptoms, and physical examination are of much greater value than any renal functional test yet devised. The phenolsulphonephthalein test used in conjunction with the clinical symptoms, history and physical examination is of value. A small percentage output should put the surgeon on his guard and cause him to study the patient most carefully before undertaking an operation. The phenolsulphonephthalein test should be used only as one of the many methods of investigation in ascertaining the condition of the patient.

Tracy studied 100 cases. The dye appeared in the urine from five to forty-two minutes, the average being ten minutes and eighteen seconds. The average output for the first hour was 34.27 per cent., for the second hour 20.83 per cent. and for the two hours 55.1 per cent. In 91.7 per cent. of the tests the output was greater in the first hour. In 8.3 per cent. of the tests the output was greater in the second hour. In 20 per cent. of the tests there was 4 per cent. or less than 4 per cent. difference between the output in the first and second hours. Five cases, with the lowest phenolsulphonephthalein output in the series, were subjected to major operations and had a normal convalescence. Other cases with a much higher phenolsulphonephthalein output had a complicated convalescence, with evidence of renal disturbances. One case with a phenolsulphonephthalein output of 53 per cent. died of uremia in less than two months. Another case with a phenolsulphonephthalein output of 72 per cent. died of uremia in less than one month. A third case with a phenolsulphonephthalein output of 55.5 per cent. died in the hospital of uremia fifty-two days after operation. A case with a phenolsulphonephthalein output of 87.5 per cent. died in the hospital of uremia five days after operation. In some cases the phenolsulphonephthalein output was less after the patients were placed in bed and the excretory organs toned up; in other cases the output increased. In determining the functional activity of each kidney, Tracy says, the test should be applied several times and the average taken. The result should then be checked up by other tests.

156. **New Method of Round Ligament Fixation.**—In Goodwin's method the abdomen is opened in the usual way, the round ligament separated, and by means of a ligature carrier, which has been thrust through the rectus muscle, drawn to the surface of that muscle. The loop of round ligament is held up by an assistant and the surgeon, either with scissors or scalpel, commencing at the site in which the ligament has been drawn through, cuts for about three-quarters of inch in length in the direction of the fibers and toward the pubis the rectus muscle and underlying tissues, including the peritoneum. The assistant then holds at the upper angle of this incision one side of the loop of round ligament and places and holds the other side in the lower angle. While so held the loop arches over the incision made in the rectus, one pillar being in the upper, the other in the lower angle. The surgeon, working under this arch, sutures together with catgut the edges of the incision in the rectus lying between the pillars held in the upper and lower angle, being careful to bring together the fibers of the muscle in the same apposition they were before incised. This leaves the loop of ligament resting on a bridge of muscle three-quarters of an inch long, one end of the ligament passing into the pelvic cavity through a small opening in the lower angle of the incision and the other through a similar opening in the upper. It is impossible for the ligament to get away from its moorings and drop back into the pelvic cavity. Although it is not necessary, the end emerging from the one descending into the pelvic cavity may be anchored at its site by passing one suture through it and the rectus muscle.

157. **Rubber Gloves: Technic of Mending.** — Cotton describes his technic as follows: Take an ordinary library filing card, spread it rather heavily with ordinary library paste, and paste on it the rubber tissue (Cotton uses dentists' rubber dam of light weight), smooth this flat, and let the paste dry. Then when a patch is needed, cut one out, rubber, card and all, to fit the tear. Put the glove on the hand, inside out, moisten the patch with cement, let it dry for a few seconds, fit it on in cases in which it belongs and press it home hard. If the tear is large it is easier to lay the moistened patch down and fit the edges of the tear to it, then press. That is all there is to it, except for powdering the glove and laying it by. Later, soak it in water and the bit of card comes away as the paste dissolves. This gives a secure patch, adherent clear to its edges, flat and water-tight, and fit to stand boiling as well as any patch is.

160. **Diverticulum of Cecum Following Appendectomy.**—Following appendectomy the pain of which Bunts' patient previously complained, entirely disappeared for nearly a year, when she began to have renewed attacks of pain in the right side. Examinations were made on various occasions and it seemed that the pain must be due to a slightly enlarged ovary on the right side. Bunts opened the abdomen through the right rectus muscle and found the right ovary slightly enlarged and cystic. As a matter of curiosity he examined the site of the previous appendiceal operation and found a distinct white ring in which the purse-string suture had been placed, but spread out to nearly three-fourths inch in diameter. From this ring there protruded a pouch like

the finger of a glove, though somewhat conical and nearly one inch in length. By squeezing the cecum, he could force this to balloon with gas. Its wall was quite thin, apparently devoid of any mucosa, and could be invaginated easily back into the cecum. Feeling that the distention of this diverticulum might be the cause of some of her colicky pain and that its extreme thinness might make it a positive source of danger from rupture, it was pushed back into the cecum and a double row of purse-string sutures applied to close the opening. Subsequent to the operation the pain had disappeared. Since this time, Bunts has examined the cecum in all pelvic operations in which the appendix had previously been removed and has found two more distinct cases, though not nearly so large as the first, but the widened ring and thin dilatable wall were plainly to be seen, and in all he followed the procedure used in the first case.

163. **Method of Drainage in Suppurative Appendicitis.**—Pettit drains in these cases close to the ilium, so that the lateral wall of the abdomen forms one wall of the sinus.

165. **Ferment Diagnosis for Cancer.**—In a series of cases of malignancy Goodman and Berkowitz were able to obtain thirty reactions out of thirty-three cases in which the results corresponded to operative post mortem and clinical findings. One case of carcinoma was not diagnosed and one negative case was diagnosed as a sarcoma.

166. **Method of Distending the Veins of Forearm.**—The method used by Hoge consists in using an inflatable rubber bag about 4 inches in width and long enough to encircle the arm (the arm-band from a blood-pressure apparatus answers admirably), with a tube attached leading to a hand pump with a screw-escape valve. The arm-band is placed in position around the arm, well above the site of insertion of needle or cannula. Inflate the bag with the hand pump. This causes a stasis of the venous circulation without perceptibly obstructing the arterial flow, and any desired degree of distention of the obstructed veins may be produced. When the needle has been inserted (closed method) or the vein has been freed and the cannula inserted (open method) turn the screw-escape valve, releasing pressure and permitting reestablishment of the venous flow. The solution may then be permitted to flow in as rapidly as is desirable.

1. **Diathermy—Its Production and Use in Medicine and Surgery.**—When diathermy is to be used for surgical purposes, Cumberbatch states the current must be led through the tissues that are to be destroyed. Two electrodes are required. One of these, the active electrode, is placed on the morbid tissue, the other, the indifferent electrode, is placed on the skin of some other part of the body. The current then passes through the body between the electrodes and heats all the tissues, both normal and abnormal, along its path. It is therefore, necessary to adopt some device so that the temperature of the abnormal tissues may be raised sufficiently high to cause them to coagulate, without at the same time injuriously heating the normal parts. In other words, the life-destroying heat must be restricted to the abnormal tissues. This will be the case if the indifferent electrode makes contact with a large surface of the body and the active electrode with a small surface of the morbid tissue. The parts under the indifferent electrode, if the latter is sufficiently large, will be but slightly warmed, because the path for the current in these parts is wide and its resistance correspondingly low. The parts in contact with the active electrode will be strongly heated because the path for the current is narrowest in this situation and its resistance highest. The highest temperature will always be in the tissue in immediate contact with the active electrode, while in the tissues along the path of the current the temperature will be progressively lower as the distance from the active electrode is increased, till at a certain distance the tissues will be outside the destructive influence of the diathermy.

This distance is determined by the temperature that is reached at the active electrode. If the temperature at this electrode is sufficient to coagulate the tissue, destruction of the latter will extend only for a short distance around. As the temperature is raised the coagulation spreads further. When the temperature reaches a certain point the tissues in contact become dry, and then they conduct the current badly, and the needle of the ampèremeter swings back toward zero. Loud crackling sparks leap over and through the dried tissue on to the moist tissue around. If the current is not switched off violent commotion ensues around the electrode, sparks dart around and bubbles of steam escape from the tissue. Coagulation spreads further and the tissue around the electrode becomes dry and hard. This stage is reached sooner when the active electrode makes a small contact with the tissue, because the smaller the contact the narrower the path for the current, the higher the resistance the greater the heat. It is advisable, when performing diathermic cautery on the living subject, to switch the current off when sparks begin to appear, because there is at this stage not a pure diathermy effect; that is to say, there is excitation of muscles and nerves as well as heat penetration. This excitation might become extremely violent.

2. **Simple and Rapid Method of Localizing Bullets.**—A method of which Hernaman-Johnson has made considerable use is the following: Suppose a bullet has lodged somewhere about the middle of the thigh. The patient is placed on an ordinary examination couch having the tube beneath. His feet are placed together, with toes pointing directly upward. The Roentgen rays are turned on with a widely open diaphragm, and the general position of the bullet ascertained by the fluorescent screen. The aperture is now gradually narrowed, and the tube moved about so that the image comes into the center of the field, which, if the anticathode has been correctly centered will be a perfect circle. This process is continued until the illuminated patch is not more than 1 inch in diameter. The image of the bullet is now vertically above the bullet itself.

The only special device necessary is now used. It consists of a metal ring having an internal diameter of about ¾ inch fixed to the end of a flat wooden handle 1 foot in length. The ring is slipped under the screen, and moved until its shadow encircles that of the bullet. A mark is made on the skin with silver nitrate in the center of the ring, the screen being first removed, but care being taken not to displace the "ring-localizer." Next, the screen is readjusted and the ring is now slipped between the patient and the couch. The encircling position is again found, and a second mark made, this time on the skin of the lower aspect of the limb. If everything has been carried out properly, this second mark will be found vertically below the first.

To ascertain at what distance below the surface the bullet will be found the patient is rolled over on his side. The original procedure is now repeated and two other marks are obtained, a line joining which cuts a line joining the first two at right angles. The patient is now returned to his former position, and an inspection of the marks will enable one to judge within half an inch the distance at which the bullet lies below the surface.

Points essential to the success of the method are: 1. The beam of Roentgen rays must be vertical, and the shadow of the bullet must be maneuvered into the center of the small illuminated field. 2. The "ring-localizer" must accurately encircle the bullet shadow. 3. The nitrate of silver marks must be placed at the center of the ring. It is better to make dots for the vertical marks, and crosses for the horizontal, in order to avoid subsequent confusion. 4. Whenever the nature of the case permits, the patient should be operated on in one or other of the positions in which the localizing was carried out. 5. Lastly, wherever possible, the patient should be taken directly from the examining couch to the operating room. Bullets sometimes alter their position to some extent even in twenty-four hours and undeserved discredit is thereby brought on the art of the radiographer.

13 *"Elderton" Method of Control in Testing Value of New Tuberculin. H. B. Shaw.
14 Artificial Pneumothorax. H. deC. Woodcock and J. A. M. Clark.

7. **Acute Appendicular Obstruction.**—Wilkie summarizes his paper as follows: Two acute pathologic processes are met with in the vermiform appendix—acute appendicitis and acute appendicular obstruction. Clinically acute appendicitis is distinguished by the signs of inflammation, there being from the onset a rise in pulse and temperature. Acute appendicular obstruction gives rise to vomiting, colicky pain, and abdominal tenderness, but at the outset to no appreciable rise in pulse or temperature. The changes occurring in an appendix the lumen of which is completely obstructed depend on the presence or absence of fecal matter within its lumen. In experimental obstruction in an artificial appendix the changes vary greatly according to the nature of the diet of the animal previous to the experiment, rich protein diet being associated with much more rapidly destructive changes than carbohydrate. Undigested protein, putrefactive bacteria and an alkaline reaction together produce rapid gangrene in the walls of the obstructed organ. The prevalence of the severe forms of acute appendicular disease in Western as contrasted with Eastern people is probably to be explained by the animal diet indulged in by the former. On the same lines may be explained the increasing frequency of such disease in large industrial areas and its relative frequency in the male sex.

10. **Antiseptics in War.**—Cheatle advocates the use of the following solution in place of iodin: a mixture of 1 in 20 phenol and 1 in 500 mercury perchlorid in absolute alcohol. It is colored with rosalin. The value of this combination is as follows: 1 in 20 phenol is a solvent of fat as well as a germicide. Mercury perchlorid is a most powerful germicide. Rosalin has an important action in being a mordant. Wherever the dye is seen mercury perchlorid is present even weeks after application. Alcohol dries sooner than water, it does not macerate the tissues so much, and it appears to encourage greater penetration of the antiseptic. No case has suffered from mercurial or phenol poisoning, although it has been applied frequently and freely to large granulating wounds.

16 Education of Semiblind. W. B. I. Pollock.
17 Esophagotomy for Removal of Tooth-Plate. W. Downie.

13. **Control Method of Testing Value of New Tuberculin.**—An analysis of eighty-four cases treated by reactionless doses of tuberculin is given by Shaw. Of 23 cases which improved, 11 had been treated with tuberculin, 12 had not. Of 29 cases which were worse, 16 had been treated with tuberculin, 13 had not. Of 32 cases which remained *in statu quo*, 15 had been treated with tuberculin, 17 had not. So far as afebrile cases are concerned, Shaw says, the reactionless dosage with tuberculin gives more favorable results than treatment without tuberculin, as far as these cases are concerned.

15. **Wassermann Reaction in Congenital Syphilis.**—Findlay and Robertson state emphatically that the Wassermann reaction at least in Scotland is practically only found in syphilis, and, if properly controlled, is a test of great diagnostic value. A condition of chronic eczema situated at the angles of the mouth and invading the mucous membrane of the lips, is often of a syphilitic nature. Congenital heart disease is not infrequently found in patients suffering from congenital syphilis, as evidenced by a positive Wassermann reaction. About 45 per cent. of cases of spastic diplegia and 60 per cent. of mental defectives also seem to be the subject of congenital syphilis, as evidenced by a positive Wassermann reaction.

21 *Insomnia and Suicide. C. E. Pronger.
22 Experiments on Germicidal Action of Colloidal Silver. W. J. Simpson and R. T. Hewlett.

21. **Insomnia and Suicide.**—The influence that slight refractive errors have in causing many of the functional nerve troubles so prevalent in these days is discussed by Pronger. Among these insomnia has naturally had a prominent place. Slight errors of refraction although not causing any visual defect, are of great importance in that they give rise to sundry neuroses. Especially, says Pronger, should these slight degrees never be ignored in any case of insomnia, because some error is nearly always present in those cases not associated with organic disease, such as tumor, kidney troubles, and the like, or with persistent pain from any cause. Insomnia is not usually the only symptom, but is generally associated with attacks of great depression, and often with giddiness or headaches. A few illustrations are given by Pronger of what can be done for the relief of insomnia, and also of some of the difficulties that have to be surmounted, particularly the scepticism of the patient as to the possibility of glasses being of use for such a purpose, especially if the sight is good or an oculist has already been seen.

27 Pneumonia with Symptoms of Appendicitis; with Expulsion of Ascaris; Two Cases. M. Lassalle.

23. **Encephalitis and Acute Ataxia.**—Guinon declares that when a child has fever and convulsions the trouble is always labeled "meningitis" and no one seems to think of encephalitis as the true cause of the symptoms. He reports two cases in detail which seemed to be actual encephalitis of a mild type, the children recovering completely. Both cases occurred during the epidemic of poliomyelitis in 1910, and each of the children had recently passed through measles. The first symptoms in one case had been sudden loss of the use of the legs, without impairment of consciousness, headache or vomiting. This period was followed by gradual loss of the intelligence; the language became that of a child a year old, with cries and restlessness, stiff neck and rigidity of the left side. After two weeks of this there were six days of torpor, apparent unconsciousness, except that the child wept. The face was very red but there was no Kernig sign nor rigidity

of the back of the neck and the eyes seemed normal. There was a general stiffness and exaggeration of the reflexes. There was also contracture on the right side of the face and left side of the body. The symptoms gradually subsided, a phase of aphasia and ataxia following, but the child entered on convalescence about the thirtieth day and in ten days was practically cured. The main reliance in treatment had been on hot baths, chloral and potassium bromid. The temperature kept about 37.5 C. In the other case headache and pain in the neck with rigidity at the back of the neck were the first symptoms to attract attention. The knee-jerk was exaggerated and the plantar reflex in extension. The face was extremely red but there was little or no fever. During the first two or three weeks there was apparent unconsciousness, incontinence, continual whining but almost absolute inertia to stimuli of all kinds but without anesthesia to pain. Then followed ten days of extreme restlessness, the choreic movements of the head causing erosions; the face was intensely red; the legs were still stiff but the child began to understand what was said to him and was able to drink and there was no further incontinence. The third phase was a rapid convalescence to a complete cure. The cerebrospinal fluid was always found normal which eliminated hemorrhage and microbian meningitis. The syndrome resembled that described by Leyden in 1868 as acute ataxia, but the incoordinate movements were not always of this type. They resembled more those of chorea at times.

26. **Tetanus from Use of Felt Pad in Treating Scoliosis.**—The cases of tetanus described here were mentioned recently in these columns, 1914, lxiii, 44.

32 Methylene Blue Test for Purity of Milk. (Les réductases du lait de vache.) G. Vitoux.

28. **Handy Mufflers for the Men in the Trenches.**—Dr. Michel, the inventor of the clips used in closing wounds, now presents a muffler for the soldiers in the field which can be used for a hood, a vest, a body band, muff or a jacket as desired. The muffler is crocheted, about 1.2 meters long by 40 cm. wide (about 48 by 16 inches). A slit 20 cm. long (about 8 inches) is left lengthwise in the center, and buttons are sewed on each end and along half of the edge of each side—about two dozen buttons in all. Crocheted mufflers are much better than knitted or cloth ones, he states. The crochet should be loose with a simple single double stitch. The large meshes permit the buttons to be buttoned anywhere in the muffler, thus fitting it to any surface. Several mufflers buttoned together make a warm blanket.

33. **Conjugal Tuberculosis.**—Levy devotes seventeen pages to the tabulated details of 317 families at Posen in which husband or wife or both were under medical supervision for pulmonary tuberculosis. They show that infection of the consort is of extremely rare occurrence although it is possible. When the consort does develop tuberculosis, it runs an exceptionally mild course. If the tuberculous husband or wife is removed from the environment, the secondarily infected consort soon conquers the tuberculosis. Among those resisting infection from their tuberculous consort there were many who were "scrofulous" during youth. The tables sustain the assumption that infection with tuberculosis occurs early in life among wage-earners. Also that an infection of this kind confers immunity to new infection later in life or, if infection occurs, the course is essentially milder.

36. **Acute Tuberculous Septicemia.**—Reiche comments on the extreme rarity of this most acute form of tuberculosis—Landouzy's typhobacillosis. It simulates typhoid and the lesions are solely those of congestion and degeneration, not reaching the stage of tubercle production as the disease either subsides to complete recovery or proves speedily fatal. In a recent case, in a girl of 18, the course was typical of this septic tuberculous typhobacillosis. No tissue reactions suggesting tubercles were found at necropsy about a month after the first symptoms had been noted. In explaining the syndrome, he suggests that the septicemia itself might have entailed the peculiar anemia and hemorrhagic diathesis, or the escape into the blood of tuberculous masses from an old cheesy bronchial gland might have failed to induce miliary tuberculosis only because the bone marrow had been suffering from a degeneration resembling that of leukemia. Still another causal possibility is that a primary anemia with pathologic reaction of the bone marrow had reduced the resisting powers of the organism to their lowest point.

43 Vaccine Therapy of Neuralgia and Neuritis. (Heilung der Neuralgie und Neuritis durch Bakterientoxine.) Döllken. Commenced in No. 46.

39. **Mycosis from Woolen Underwear.**—Isaac says that a number of cases of a puzzling skin affection which simulates psoriasis or syphilids have been encountered with the onset of cold weather. They proved to be a fungus trouble, and he has traced the fungus to woolen sweaters and woolen underwear that had been laid away during the summer and then put on without washing.

42. **Sterilization with the Roentgen Rays.**—Görl reiterates that when on account of constitutional disease it becomes necessary to prevent further conception, operative sterilization should be recommended for women under 40. After that age Roentgen exposures answer the purpose fully as effectually and with the minimum of discomfort, as also when an operation is contra-indicated on account of heart or kidney disease, diabetes or hemophilia. He discusses the literature on the subject and the technic. A 3 mm. aluminum filter guards against mishaps.

48 *No Transmission of Nervous Irritation from One Eye to the Other. (Ueber sympathische Reizübertragung.) A. Elschnig.
49 *Lipoid Substances in Sediment of Children's Urine. E. Reinike.

44. **Erysipelas.**—Jochmann comments on the rarity of erysipelas among the wounded now, but adds that when it does occur the prognosis is unusually grave on account of the superposed damage from the wound. The mortality from erysipelas of the face is generally accepted as between 3 and

5 per cent. but involvement of the larynx is liable to prove fatal unless tracheotomy can be done in time. Sepsis following erysipelas generally runs a particularly severe course. He has tried all kinds of treatment and found that the simplest measures seem to be as effectual as any. All owe their efficacy mainly to the tendency towards spontaneous subsidence of the erysipelas. He now uses almost exclusively merely cooling applications of aluminum acetate or a boric acid solution, frequently renewed. The patient finds this refreshing. For the face he applies boricated petrolatum on gauze. To keep the process from spreading, he applies a broad constricting band or straps the region with plaster and has found these occasionally but not always effectual in keeping it within bounds. Local application of superheated air has given rather favorable results in the hundred cases in which he has induced hyperemia in the region by this means. Antistreptococcus serum has also impressed him favorably by its influence on the general condition. The pulse grew better and the mind clearer, but no special influence on the local process was apparent.

45. **Tetanus.**—Kocher analyzes recent literature on the treatment of tetanus and reiterates from his own experience that general anesthesia may tide the patient through severe convulsions. He mentions also that rhythmical inhalation of oxygen under an atmospheric overpressure of 3 cm. water put an end to the menacing cramp of the muscles of respiration in a case recently reported by Jehn in which the paralysis of respiration persisted after severing the phrenic nerve on each side. Kocher has had six adult patients with extremely severe tetanus recover under intraspinal administration of magnesium sulphate supplemented by intratracheal inhalation of oxygen and tracheotomy. With the Meltzer technic tracheotomy is not necessary.

Wicki ascribes the action of the magnesium sulphate to dehydratation of the spinal cord and nerve roots by the drug, and this would explain the transitory nature of the effect and the lack of any permanent injury from it. Kocher emphasizes that the desired influence on the tetanus can be counted on only when the full dose has been given, that is, enough to cause the complete relaxation of the contracted muscles. If one injection does not suffice, others must be given, and thus kept up until the tetanus toxin in the body has exhausted its effect. He has repeated the intradural injection as many as ten times. Hotz has reported two cases of recovery under subcutaneous injections of magnesium sulphate; one patient was given 40 gm. twice a day for five days.

Kocher advocates a preventive injection of 10 or 20 gm. of antitetanus serum for every wounded soldier; on the slightest sign of tetanus, a supplementary injection under local anesthesia of 10 c.c. in the vicinity of the wound and in exposed muscle tissue, supplemented by endoneural injection to block the nerve and, further, intraspinal injection of 10 c.c. after allowing about that amount of fluid to escape. The wound is to be cleared out and kept open, protected only with a thin layer of gauze. If the patient is a vigorous man, from 30 to 45 gm. of a 25 per cent. solution of magnesium sulphate should be given by subcutaneous injection if the reflex excitability is increased and the muscles are stiff, repeating the dose if the symptoms persist or become mildly aggravated, reenforcing these measures at need with large doses of chloral—at least 2 gm. at a dose up to 12 gm. in the twenty-four hours. If the symptoms grow worse, 10 c.c. of the 15 per cent. solution of magnesium sulphate should be injected into the dura, the patient reclining flat with head raised. If the muscles do not relax in fifteen minutes, the neck and head should be lowered. When the symptoms and condition permit, the subcutaneous can be substituted for the intraspinal technic or chloral can be given the preference. The intraspinal injection is liable to induce paresis of the bladder, so evacuation of the bladder must be supervised, and the menace of paralysis of the respiration must be constantly borne in mind. An ample supply of water must be ensured and the bowels kept open with glycerin enemas. Cooling of the body with ice-bags seemed to have favorable influence in some of his cases.

47. **Injury from Exploding Shell Without Direct Contact.**—Harzbecker analyzes four cases of hemiplegia following the air concussion from a shell bursting from six to twelve feet away. The symptoms and course of the disturbance indicate that the air concussion burst a blood-vessel in the brain, lung or eye. In two cases there was a typical apoplectic attack, leaving hemiplegia. When such a concussion proves immediately fatal without signs of external injury there is probably some small hemorrhage into some vital part, like the respiration center, or profuse internal hemorrhage.

48. **No Transmission of Experimental Irritation from One Eye to the Other.**—Elschnig found that the composition of the vitreous humor—as indicated by the refractometer—is constant in the rabbit eye. The difference between the two eyes is zero or a very minute fraction. This permits instructive experiments with irritation applied to one eye, as transmission of the irritation to the other eye would be at once evident in the refractometric findings. His numerous experiments were constantly negative. Even injection of croton oil or subconjunctival injection of strong salt solution failed to induce any signs of irritation in the untreated eye at any time during the following two weeks. The research was done on rabbits, monkeys and dogs under general or local anesthesia and led to nothing which can serve in any way to sustain the assumption of sympathetic transmission of irritation by way of the nerves as the cause of sympathetic ophthalmia.

49. **Lipoid Substances in Children's Urine.**—Reinike examined with the polarization microscope the urine of a hundred children and found a lipoid in the sediment in eight cases. In four the findings were brief but in the others the lipoid content kept constant through weeks and months. In two of these cases the kidney was the seat of chronic degenerative processes with edema, ascites and uremic attacks. The first was a girl of 12 and the kidney disease was of two years' standing. The other was a girl of 4 with serious kidney disease for ten months. No preceding infectious disease was known in either case. The two other children presented symptoms of a mild kidney trouble and only the discovery of the lipoids in the urinary sediment suggested the severity of the kidney disease, confirmed by the course of the cases. The discovery of these optically active lipoids in the urine sediment thus serves to differentiate even in children degenerative kidney disease from the inflammatory and functional. He never found such large proportions of these lipoids in children as he has found in some adults, especially in one adult case of syphilitic disease of the kidney. On the other hand, he has never found them in the urine of healthy children or in those with acute disease.

57 Influence of Balneotherapy on the Concentration of the Blood in the Capillaries. J. Löwy.
58 *Treatment of Decubitus. O. Nordmann.

51. **Oxygen in Treatment of Gas Phlegmons.**—Sudeck reports that he was able to save not only the life but the limbs of two men each of whom had had the bone in one arm much shattered and an extensive gas phlegmon had developed in the purulent wound. Thiriar plays a jet of oxygen on the raw surface after amputations, but Müller introduces the oxygen directly into the tissues through a stout cannula, and does not think it necessary to open up the phlegmon otherwise. It is this technic which Sudeck applied, pushing the cannula down into muscle tissue. The part swells up, but this subsides as the oxygen is gradually absorbed. The oxygen emphysema is still perceptible for

several days. As gangrene sets in so promptly from a gas phlegmon, he urges that no time should be lost before applying the oxygen. The German hospital trains, he says, now carry tanks of oxygen for this purpose.

54. **Chilblains.**—Schwering paints the region with tincture of iodin without preliminaries and then swabs the region, as soon as it is dry, with pure ichthyol. Then he presses cotton down into the sticky ichthyol until no more will stick. The stocking or glove protects the region, and the dressing is kept dry and left unmolested for from three to five days. Itching is relieved at once, and he has never known this treatment to fail.

55. **Sugar Solution in Treatment of Leukorrhea.**—Zweifel was impressed with the fine results reported by Kuhn and Bäumer from the use of sugar solution in treatment of gynecologic affections, as also with Magnus' success with it in 100 cases of acute or chronic osteomyelitis. Magnus and Bäumer use the sugar in substance, pouring from 150 to 250 gm. on the wound. Sudeck has applied the sugar treatment in sixty-six cases of leukorrhea of long standing, rebellious to all other measures. He used a 50 per cent. solution for rinsing the vagina or had the woman dissolve in the irrigator two tablespoonfuls sugar in two tablespoonfuls of hot water. When cooled sufficiently, this was allowed to flow into the vagina after she had settled down in bed for the night. This was repeated after eight or ten days, and over two-thirds of the women returned then to extol the improvement or cure.

In the few cases in which the sugar treatment failed to realize a complete cure, he ordered vaginal injection of a 0.33 or 0.5 per cent. solution of lactic acid after swabbing out the vagina with a 5 per cent. solution of silver nitrate. In thirty-eight cases in which this treatment was applied, there were no failures. The bacteria in the vagina were sensitized, as it were, by the nitrate so that they succumbed more readily to the action of the lactic acid. He orders the latter diluted with equal parts water; a teaspoonful of this to a pint of water for the douche.

58. **Treatment of Decubitus.**—Nordmann advises dry powders in treatment of decubitus unless there is much discharge when treatment as for any discharging wound is preferable. If there are complications or if the necrosis is extensive, nothing can compare with the continuous bath in treatment of decubitus. Not the least of its advantages, he remarks, is that the body floats to a certain extent in the water and thus further pressure on the region is avoided.

59. **Calcium Chlorid in Treatment of Tics.**—This last communication from the late Professor Emmerich gives a review of the literature on the treatment of nervous disturbance with calcium salts. Much evidence has accumulated that the functioning of nerves and muscles is dependent on the normal course of calcium metabolism. O. Loew has apparently established that the normal functioning of the cell is controlled by the calcium content of its nucleus, and others have shown that administration of calcium salts reduces to normal the exaggerated excitability of certain nerves. These and other data cited justify systematic calcium treatment of spasmodic twitching of all kinds, especially as we know that no gross anatomic basis can be discovered for *tic convulsif*, for example. The success from systematic administration of calcium chlorid in the two severe and chronic cases of *tic convulsif* reported amply confirm the above views. The first patient was a locksmith of 49, who for twenty years had suffered from chronic spasm of the muscles in the neck and right arm, and they had gradually increased in intensity during the last ten years until there were forty-five a minute and the muscles had become enlarged, while the man was becoming so exhausted that a fatal outcome was imminent. At each spasm the head was twisted around. Except for potatoes, he seldom or never took vegetables, fruit or milk, although his diet was plentiful, mostly eggs, meat and bread. The calcium content of this diet averaged only 0.721 gm., while the magnesia content was 1.113 gm. A solution of 100 parts pure crystallic calcium chlorid in 500 parts distilled water was ordered, a teaspoonful three times a day. By the fourth month there were only eight spasms a minute, and by the eighth month the tic was entirely cured and the strength regained. Equally good results were realized from the same treatment in a case of spasmodic rotation of the head from spasm of the splenius capitis. By the fifth month the patient, a letter carrier, was entirely free from his *tic rotatoire*.

63. **Field Operations.**—Perthes remarks that when an operation has to be done at once it is a comfort to realize that bacteria do not hop, like fleas, but can be kept out of wounds when direct contact is prevented. Important points to bear in mind are to use as few instruments as possible, sterilize by boiling when steam is not quick enough, use small aprons of rubber tissue at need, boiling them with instruments, sterilizing the hands with alcohol alone when there is no water to wash them. Rubber gloves are the main reliance in military surgery and protect against infection. A forehead lamp with powerful dry battery hung from the belt is a great assistance or an acetylene bicycle lamp. These lamps are too clumsy to be fastened to the forehead, but a reflector can be worn there.

70 *Continuous Bath in Treatment of Phlegmons. M. Riehl.
71 *Cholera and Vaccination. L. Arzt.
72 Conservative Treatment of War Phlegmons. (Die Kriegsphlegmone.) E. Suchanek.
73 Comparative Meteorology of Winter Seaside Resorts. E. Homa.

70. **The Continuous Bath in Treatment of Phlegmons.**—Riehl deplores that greater use is not made of the local benefit from the continuous bath in treatment of burns and extensive wounds. The pain of a severe wound is relieved at once and, as there are no dressings, the discomfort from change of dressings is avoided. The suppurating surface is kept constantly clean by being laved with the water, and he has seen many remarkably prompt cures under it. He has recently been applying this method for progressing phlegmons and has found it so effectual that he commends it to all when incision and draining do not arrest the progress of a phlegmon or when threatening general symptoms develop. The tub must be at least 110 cm. long; a blanket and some hair cushions will protect the body from contact with the metal. The water should be of the temperature most agreeable to the patient and, to keep the heat in, the tub should be covered with boards and blankets. It is not necessary to have a constant supply of fresh tempered water. The patient can be transferred to another tub after a few hours. He can be lifted on a sheet at need. The continuous bath is particularly useful for decubitus.

71. **Cholera.**—Arzt had 24 per cent. mortality in his twenty-five cases of cholera. He has the body rubbed perseveringly with spirit of camphor during the painful cramps and injects

salt solution, sometimes using a 1.5 per cent. solution. After the patient has thus been tided past the first collapse, he gives bolus alba systematically and repeats the saline infusion twice a day. Three of his patients had a pronounced eruption during the cholera. One of his attendants contracted cholera thirty-eight hours after the first anticholera vaccination. The second vaccination followed in five days, and two days later she developed cholera, but it ran a mild course with complete recovery in five days. One man was vaccinated during the incubation of cholera and except for vomiting he had no further symptoms of cholera. There were no serious by-effects from the anticholera vaccination in any instance.

77 *Hydronephrosis; Twenty Cases. W. V. Simon.

77. **Hydronephrosis.**—This communication from the University surgical clinic at Breslau reports that the hydronephrosis was certainly congenital in 13 and probably congenital in 2 more of the 20 cases reported. The ages ranged from 6 months to 67 years. There was some deformity in the kidney or its vessels in 3 of the cases,, and acquired causes were evident in 7, including 4 of trauma and 1 of obstruction from gravel. In 5 cases there was some concomitant affection, pleurisy, peritonitis, chronic pancreatitis, interstitial nephritis or severe arteriosclerosis. When the hydronephrosis is intermittent and not very serious and is evidently brought on or aggravated by movability of the kidney, attempts to restore the kidney to place without an operation are justified. Massage, bandages, etc., may answer the purpose. If there is no or very little functionally capable kidney tissue left, nephrectomy should be considered if no tumor or stones or abnormal vessels can be found to explain the hydronephrosis. The urine on the side affected may contain blood, but in 2 of the cases reported blood was found in the urine from both kidneys and albumin in 2 cases. All the abnormal findings in the urine may disappear during the intervals between attacks. The distended kidney in one case projected past the median line so far that the tumor seemed to be on the sound side. Generally a prolongation of the tumor into the kidney region can be palpated. Remnants of kidney substance may form knobby protuberances that can be palpated on the surface of the kidney. An important differentiating sign is the persistence of the area of dulness in the same spot on change of position.

He does not approve of exploratory puncture on account of the danger of infection, as, for instance, with echinococcus disease. The contents of the hydronephrotic kidney may resemble the fluid in an ovarian cyst so that puncture may prove misleading. The 20 cases are described in detail. Nephrectomy was done in 9; in 5 not until after the sac had been sutured to the skin and tapped. In 3 a conservative-plastic operation was done. One patient with an old (seven months) and infected hydronephrosis died soon after the operation and one from after-hemorrhage and embolism. In 3 other cases the hydronephrosis was probably infected, but 2 of the patients were cured; the outcome in the other case is not known. The conservative-plastic operation did not cure the hydronephrosis in one of the 3 cases and 2 were only improved in the 9 nephrectomy cases. The other surviving patients were all cured by the intervention.

November 28, XLI, No. 48, pp. 1705-1720

78 *Symptoms in Genital Organs with Appendicitis. (Untersuchung auf Genitalsymptome zur Unterstützung der Diagnose bei Appendicitis.) O. Lanz.

78. **Genital Symptoms in Appendicitis.**—Lanz corroborates ten Horn's statement in regard to the pain elicited by pulling on the right spermatic cord when there is acute appendicitis (mentioned in these columns recently, July 4, p. 69). Lanz has found a number of other differentiating phenomena, as he illustrates by eight typical cases. Particularly in children, frequent and painful micturition is often an early sign of appendicitis. In both children and adults, when the forefinger is worked into the inguinal canal on the left side no appreciable resistance or pain is experienced, but on the right, if the appendix is inflamed, the muscles contract as the finger is introduced into the inguinal canal so that it is impossible to work it in deep, and if the patient coughs while the finger is in the canal, there will be local pain. The spermatic cord is also painful on pressure when it is pulled, and when it emerges from the canal it is swollen and tender. The cremaster reflex on that side is usually weak or abolished entirely with acute appendicitis. If the appendix is situated abnormally low, muscular rigidity and tenderness may be found in the lumbar region or may be detected through the rectum. Lanz has previously called attention to the relaxation of the sphincter muscle when the pouch of Douglas is being invaded. When there is actual suppuration in the pouch of Douglas, the sphincter may gape completely.

79 *Apparatus for Measuring the Roentgen Rays. (Das Iontoquantimeter; ein neues Messgerät für Röntgenstrahlen.) H. Meyer.

November 28, No. 48, pp. 1441-1464

80 *Mesothorium in Treatment of Cancer in Female Genital Organs. J. Braude.

79. **Apparatus for Dosage of Roentgen Rays.**—Meyer gives an illustrated description of the iontoquantimeter for measuring radiant energy. It is based on the physical phenomenon that air which is absorbing Roentgen rays becomes a good conductor for the electric current. The electrometer dial thus indicates the amount of rays being absorbed. It shows further, he explains, the surface energy and the degree of hardness of the rays, and thus he thinks we get an absolute measure of the radiant energy being applied.

80. **Mesothorium in Treatment of Cancer of the Uterus.**—Braude describes his experience in this line in 44 cases at Strassmann's gynecologic clinic since October, 1913. The reaction to the mesothorium exposures is as a rule proportional to the extent of the cancer, and thus serves as a basis for the prognosis. In 2 cases the reaction was so intense that the patients succumbed. The technic has been modified since so that an interval of several weeks follows each series of eight or twelve exposures in the course of two or three weeks. One is clinically cured of the 2 patients with inoperable cancer previously cauterized. In the 7 cases of inoperable recurrence after an operation, 2 of the patients are clinically cured; 2 have died and the outcome is not known in the other cases. Eight of the 10 operable patients are clinically cured and 3 of the 6 whose general condition forbade operative treatment. He bases the assumption of a clinical cure on the improvement in the general condition and weight as well as the local healing of the lesion. The invariable cessation of menstruation shows that the ovaries have felt the effects of the rays, and this gives grounds for assuming that the tissues between the ovaries and the mesothorium in the vagina have also felt the effect of the rays. In the bleeding inoperable cases, with fetid discharge and great weakness, the benefit from the mesothorium was beyond anything yet realized by any means outside of radiotherapy, and it has lasted for about a year to date in the typical case described.

Zentralblatt für innere Medizin, Leipzig

November 14, XXXV, No. 46, pp. 1001-1016

81 Heart-Block with Paroxysmal Auricular Flutter. (Fall von Herzblock mit paroxysmalem Vorhofflimmern.) J. S. Schwarzmann.
82 *Angina of the Abdomen. (Zur Symptomatologie und Therapie der Angina abdominis.) M. J. Breitmann.

82. **Angina Abdominis.**—Breitmann has had a number of patients with attacks of pain in the abdomen, meteorism and other symptoms closely analogous to those of angina pectoris and due to arteriosclerosis of the abdominal vessels or vascular cramp. The patients were usually men, including many syphilitics and others inclined to abuse of alcohol or tobacco. Relief followed escape of gases; they were probably the result of arteriosclerotic paresis of the intestine and ischemia interfering with peristalsis and absorption. Pallor, vertigo, syncope for a few minutes or hours, and the radiation of the pain to the heart and the left shoulder are characteristic, as also abnormal pulsation in the region of the abdominal aorta or epigastrium. The region of the abdominal aorta and a point toward the right on the line joining the ninth ribs were especially sensitive. The colic pains occurred periodically in various parts of the abdomen, generally at the hieght of digestion, and were accompanied by distention, fetid stools, eructation and vomiting as a rule. The free intervals might be months in length. The nocturnal attacks of pain were the most severe. The blood-pressure was often but not always high during the attacks. In one case the woman had had spasms of colic about once a year from childhood, but in the last three years they came oftener and were sometimes accompanied by vomiting of blood, but energetic palpation during and after the attacks never caused pain; ergot gave relief in this case. In some cases the trouble seems to involve the stomach and heart; some reflex action from the irritable stomach exerts a depressing or paralyzing influence on the already oversensitive and functionally weakened heart. Sudden death with consciousness unimpaired is common in this type, which is usually a syphilitic angina pectoris or abdominis. It is generally mistaken for a gastro-intestinal trouble until necropsy reveals the arteriosclerosis of the abdominal vessels. Especially with syphilitic disease of the abdominal aorta, the pain is intense and the patient can get relief only in the knee-chest position.

November 8, XXI, No. 45, pp. 1569-1600

86 *Modified Bassini Operation for Inguinal Hernia. (Modificazione al metodo Bassini nella cura del laparocele inguinale.) O. Tenani.

86. **Modified Bassini Operation.**—Tenani's modification aims to reenforce the weak point in the abdominal wall by *superposing* the aponeurosis above and below. After the usual Bassini technic he sutures the internal oblique and transversalis muscles and the fascia transversalis to the posterior margin of the gap, and the upper flap of the aponeurosis of the external oblique. In making this fourfold layer he is careful to keep all the fibers in their natural position in regard to each other. Then he slits the margin of the aponeurosis across, on a line with the internal inguinal ring, slitting thus both the upper and lower flaps of the aponeurosis. The edges of the two flaps thus formed are superposed and sutured under the cord, drawing the whole toward the median line. In cases of an exceptionally large opening he resects some of the aponeurosis. He has operated with this technic in numbers of cases with permanently good results in all. The superposed flaps of aponeurosis form a stout pad around the cord. The opening left is more oblique than in natural conditions, which is an additional barrier against recurrence. These advantages far outweigh the drawback that the cord is left to run subcutaneously. None of his patients and none of Postempki's seventy-eight has had any inconvenience from this subcutaneous location of the cord, while all have been permanently cured of the tendency to hernia at this point. He gives the details of fifteen typical cases.

94 *Pain from Minute Uterine Fibromas during Pregnancy. (Des accidents douloureux qui accompagnent les petits fibromes utérins pendant la gestation.) G. Stavridès.

94. **Pain from Small Fibromas in Pregnant Uterus.**—Stavridès reports three cases in which fibromas—too small to be detected outside of a pregnancy—suddenly became enlarged and painful at the fifth or sixth month of pregnancy. Each could be felt as quite a large tumor sessile on the uterus and causing a slight reaction on the part of the peritoneum. Under repose and moist heat the disturbances subsided and the pregnancy progressed unmolested to term. Palpation three months later failed to reveal any trace of the tumor. It evidently had been located in the parenchyma, but under the stress of the pregnancy had parted the fibers in the wall of the uterus and forced its way to the outer surface. In a later pregnancy in one of the cases there was no disturbance from the minute fibroma, although it must still have been in its place in the uterus wall.

CONCERNING THE RESULTS OF OPERATIONS FOR BRAIN TUMOR[*]

HARVEY CUSHING, M.D.
BOSTON

The broad topic under discussion, the Surgery of Brain Tumors, has many aspects—so many in fact that merely to touch upon all of them would be impossible in a single session. I shall endeavor therefore to confine myself solely to that portion of Professor Küttner's all too brief paper which deals actually with the operative results attained in the Breslau clinic, and shall make no comment on other matters such as earlier diagnosis, Hirnpunction, choked disc, palliative decompression, callosal puncture, the technical features of a craniotomy and so on, though each of them is worthy of detailed consideration.

Any attempt to give a general survey of the subject would lead us as far as would a similar survey of, let us say, the surgery of abdominal tumors—and not long ago, when abdominal explorations were less common, elaborate reports which were made to include the statistical results of operations, were written on this far-reaching subject. A comparison of the operative results, even in the case of specific lesions of specific organs, at the hands of one or another surgeon is sufficiently odious, but when it comes to drawing statistical comparisons of operations for all tumors of all the tissues occurring in all parts of one of the body cavities the proceeding is futile. This is just as true of the intracranial chamber as it is of the abdominal cavity.

In the first place there is no uniform classification for the multiform growths that arise from the meninges and ependyma, from the central or peripheral nervous tissues themselves, or from the epithelial organs, pineal, pituitary and choroid, pertaining thereto. Furthermore, the situation of the lesion is often of importance even greater than its histological nature: whether it arises above or below the tentorium, in the right or left hemisphere, or is superficial or deep; whether it involves relatively "silent" areas or, on the other hand, areas important for life, as the repiratory centers, those important for intellect, for perception or expression, those important for sensation, locomotion, or co-ordination of movements; whether it produces symptoms confined to its immediate neighborhood or distant symptoms through oedema or cerebrospinal fluid obstruction; whether it has led to a great increase in intracranial tension, or the phenomena of this condition are absent; whether it affects special sense tracts or organs, particularly those for sight; whether it produces constitutional symptoms through disturbances on the part of the intracranial glands of internal secretion, and so on—all of these factors so modify the conditions attendant upon an intracranial growth as to make the bare enumeration of operative recoveries meaningless.

The mere feat of removing a tumor is not the only thing to be borne in mind, for this is a sorry accomplishment if the patient is left blind, palsied, aphasic, epileptic, or continues to be intellectually or physically crippled in any way. As Professor Küttner points out, the relief afforded by a well conducted decompression in the case of a tumor which occupies a relatively mute area may be as great and as enduring as when a growth is actually removed from a part of the brain of greater importance to the individual. Many tumors, moreover, are very slow growing and may reach an amazing size before any pressure discomforts or disturbances of vision occur, so that palliative measures, if undertaken at all, guard merely against some future contingency, and an effort to enucleate the growth, even if it is accessible, may be seriously meddlesome. Hence many tumor operations are undertaken only as a last resort, not alone because of tardy diagnosis, but through deliberate choice.

In view of all this there will necessarily be many individual standards for what is to be regarded as "recovery" from an operation for brain tumor. To some it is the actual extirpation of the lesion with preservation of life, but if a high grade of choked disc subsides with greatly lowered acuity of vision, one of the worst symptomatic complications of an intracranial growth persists; if cortical epilepsy continues after the growth is removed we can hardly be jubilant over its removal. If therefore a strict construction is put upon the word "recovery," as it should be, probably none of us see more than a possible 5 per cent. of our patients so "cured." If we can rest content with some persistence of symptoms after a tumor removal possibly an additional 10 per cent. are in this sense "cured," and the individual may lead an effective life, just as he may on recovery from a minor apoplexy which has possibly left some permanent trace of its occurrence. However, if satisfied with alleviation of suffering, preservation of vision and prolongation of life in relative comfort and usefulness, often for many years, certainly 50 or 60 per cent. of all patients can thus be helped. But in any event, even under the most favorable surroundings and with the widest experience and greatest skill it may be expected that 15 or 20 per cent. of the cases will continue helpless from an uninterrupted progression of symptoms and that a possible 10 per cent. will succumb to the operation, owing usually either to unavoidable loss of blood or to pressure implication of the respiratory center, which as all have observed is particularly apt to occur after subtentorial manipulations.

---

[*] From the Peter Bent Brigham Hospital.

[*] An amplification of a discussion of Prof. Küttner's paper, "The Results in One Hundred Operations Performed on the Diagnosis of Brain Tumor," read before the Section on Surgery at the Sixty-Fifth annual meeting of the American Medical Association in Atlantic City, June 23, 1914.

Obviously, statistics collected from the literature in general are utterly worthless for the purposes which chiefly concern us—namely, the immediate operative mortality and the late results of these operations. Indeed even in the operative series of one individual or of one operative clinic, dependable information concerning these two matters is difficult to secure and a reliable estimate in percentages difficult to make.

A statistical presentation of the results of a comparatively uniform procedure, such for example as the amputation of the breast for malignant disease, becomes complex enough if we go beyond the simple percentage record of immediate surgical fatalities. An arbitrary three-year period of life without apparent return or continuance of the growth was once accepted as the standard of cure, but all of us have seen fatalities after ten or twenty years, or indeed in rare instances have seen patients carry a slowly withering breast cancer without operation for an equal length of time. A number of the patients in my brain tumor series have died from multiple cerebral carcinomatosis, one of them eight and another ten years after an operation for cancer of the breast which had been recorded as cured. Then too in the last twenty years we have seen not only a vast improvement in the breast operation itself, but a consequent readiness of patients to accept early intervention, so that the operative results of the past few years must necessarily be better than those of a decade or two ago; yet while we wait for the statistician to show this the operation will probably improve still further. Thus the prognosis of this year's cases may and should be vastly better than that of a similar group of cases ten or five or even three years ago.

So in brain tumor operations, our present statistics, if they lead us back a few years, must necessarily be built up from the results of operations upon patients with advanced disease, and what makes the matter worse, from the results of operations which in the light of our present knowledge were badly conceived and improperly conducted. Hence, for data concerning permanence of results we must depend on the figures of an era of relatively crude surgery for the figures of a recent era are instructive only from the point of view of immediate mortality. Some years ago a leading neurologist reported one of my cases of cerebello-pontine tumor as the single example in his experience of complete cure of a brain tumor with total disappearance of all symptoms following extirpation of the lesion. Three years later a second operation of the same type was necessitated owing to a reappearance of symptoms from continuance of the growth. In 1904 I removed from the right hemisphere in a young man a large tumor which proved to be a glioma. He remains, after ten years, absolutely free from symptoms, but will this be final in view of the nature of the lesion? In other words, from what we know of gliomata is the patient in a strict sense "cured" of his disease? Then how may we classify the large number of patients presenting a tumor syndrome but in whom no lesion has been certified by operation—lesions which for the nonce may have to be designated as pseudo-tumor cerebri? Often time alone can tell, and in my series cases thus catalogued are continually being reshifted to the true tumor group or elsewhere as further operations become necessary or post-mortem tidings are secured; but many of these individuals, with a competent decompression, live in comfort for years, even if in the end the lesion proves to have been a tumor. Further difficulties arise in connection with the statistical recording of individuals carrying lesions which will ultimately be fatal and yet in whom an immeasurable degree of palliation is afforded by a decompression or a partial tumor removal. I may cite one or two examples of patients who at the present moment are causing me anxiety.

Twelve months ago a physician traveled safely across the continent with a cerebellar lesion which had been permitted to advance so far that not only was he victimized by the characteristic cerebellar syndrome and by the severe headaches, vomiting and choked disc of an obstructive hydrocephalus, but there occurred every few days attacks lasting several hours, of agonizing suboccipital pain, accompanied by opisthotonos and Cheyne-Stokes respiration. In any of these seizures a fatal issue might have been expected. A wide suboccipital exploration was made, and after a ventricular puncture to lower the extreme tension the dura was opened and the edge of a vascular tumor was seen at the side of the right hemisphere. His condition was such as to preclude any attempt at extirpation, and as prompt and complete relief was afforded by this decompressive measure he returned home and actually resumed his practice for six months.

Some return of discomfort brought him back at the end of this period, and a large, exceedingly vascular tumor, the exact cytological diagnosis of which has led to some discussion, was incompletely enucleated from the hemisphere, with so persistent hemorrhage that finally a large piece of muscle was taken from his leg and implanted at the base of the bleeding cavity, after which, owing to his great exsanguination, a blood transfusion had to be made. Here was a close call to an operative fatality, but again his recovery was excellent, and though after this session a unilateral asynergia persisted he traveled and conducted his affairs in comfort.

Now, six months later, having been very well in the interval, he again returns, owing to threatening pressure discomforts. A further attack on the lesion can accomplish no more than the last and is even more likely to be fatal, yet it offers him his only chance of the few more months of comparative activity and freedom from headaches which he eagerly desires. Ultimately, on this basis, whether at the next or a later session, the case will have to be recorded as an operative fatality, unless I balk at what I conceive to be my duty; and without operation he may drag along with increasing discomfort for possibly a year or so.

The other patient to whom I shall refer had a large glioma involving most of the left temporal lobe, which sixteen months ago, after three more or less desperate operative sessions, was in a large part removed, fortunately without injury to her speech mechanism. Until the last few weeks she has been in flourishing health; she has gained 20 pounds in weight, has conducted her complicated household affairs and has traveled abroad. The growth proved to be a glioma, which appeared to be undergoing degenerative changes, and yet there is now a slight fulness at the seat of the operation. In view of her returning headaches should she, at some possible risk of life, be subjected to a further operation at this time?[1]

---

[1] Since this writing both of these patients have been operated upon with a fatality from hemorrhage in the first and a good recovery in the second after an extensive tumor removal.

How shall cases such as the above be classified in the event of death at some future operation? My series contains many examples of this nature with a fatality after a third or even a fourth operation, months or years intervening. From an operative standpoint some credit, it seems to me, should be given for these long periods of release, and hence my analyses will include not only the mortality percentage for the number of patients but also the percentage for the number of operations performed. This is apparently a matter which concerns my clinic more than those of others, for elsewhere, as we shall see, patients are far less often reoperated upon.

Only within the last few years has access through publication been given to the surgical records concerning brain tumors in institutions where comparatively large numbers of these cases have been operated upon. Of the two reports most worthy of consideration one was presented before the London International Congress by Howard H. Tooth[2] and was prepared from the records of the National Hospital during the ten years from 1902 to 1911 inclusive. It is an elaborate study of 265 cases operated upon by Victor Horsley and his colleagues. The other, by von Eiselsberg and Ranzi,[3] presented in the same year before the German Surgical Congress, gives an analysis of 168 cases operated upon in the former's clinic in Vienna, covering a period also of about ten years.

Unfortunately the operative statistics of 109 operations for "tumors of the brain substance" given in Fedor Krause's[4] recent volume and prepared by his assistants are too meagre to be of any great value for a comparative study and are a little difficult to interpret even in their rough details. Finally, those now presented to us by Professor Küttner from his clinic in Breslau, covering a period of six and a half years, comprise 104 surgical interventions in 100 patients with tumor or presumed tumor.

Unquestionably the striking thing in all of these reports is the high operative mortality—a mortality which is too great, I think, to be glossed over by reference to the distressing alternative of the disease left to pursue its own course. In the Breslau series the mortality was 45 per cent., and Professor Küttner estimates the Berlin mortality at 50 per cent. and that of the Vienna clinic at 38 per cent. Tooth's figures, moreover, would lead one to believe that the London operative mortality has been equally staggering.

But here again we are confronted with different standards and personal equations. Tooth in particular has endeavored to fit his analysis to different conditions by tabulating the results of the various operations for the various lesions in the various anatomical subdivisions of the brain. As he admits, the analysis becomes so involved as to necessitate an appendix in which the histories of the 265 cases are individually abstracted; and the tables fail to show the great benefit which the operation has afforded in very many of the cases which fall in the columns of the late or remote fatalities. Cases such as the two of which I have here briefly given the story, if now operated upon without another temporary success would on this basis fall among the immediate operative fatalities, with no credit for the year's relief.[5]

One might indeed assemble his cases into an infinite number of subdivisions—into those fatal at a first operation, those which recover but are unquestionably made worse; those which recover, unaffected and unrelieved; those which recover and in varying degrees are relieved; those which after a period of relief succumb to a second operation; those which remain permanently relieved; those which are explored; those simply decompressed; those in which a partial or total extirpation is carried out—and so on for each part of the brain until we are too addled to figure.

In giving statistics on such a complex subject as that under consideration no one quite knows what the future reader may be seeking. Thus, for our present purposes, the data given by Krause is insufficient. I cannot quite make out whether his tabulated 109 operations include merely all of the cases in which the tumor has been certified by operation or after death, or whether they include also the cases subjected to palliative measures alone. The number surely does not represent his entire series, for in his list of tumors the syphilomas, for example, and the various cysts which he must have encountered do not appear, and an identification of the lesion in 81 cases out of 109 operations is surely a very high percentage. He records that in 19 cases a one-stage operation was planned, with 20 per cent. mortality after the first stage and 20.85 per cent. (?) mortality in the remaining 72 cases which came to a second stage. If these figures are correct it would give an operative mortality of something over 40 per cent. Most of the fatalities were attributed to cerebral softening, to hyperthermia and to pneumonia. This it is most difficult for me to understand, for certainly hemorrhage and respiratory failure from medullary implication, and what we loosely designate as shock, is what most of us chiefly apprehend.

In Eiselsberg and Ranzi's admirable study of their 168 cases, which include a greater number of hypophysial tumors than occur in the other series mentioned, there were 61 operative deaths, 20 from meningitis or sepsis following a cerebral prolapse; 31 attributed to shock or respiratory failure, and the remainder to pneumonia or other complication—an operative mortality of 38 per cent. Professor Küttner states that 45 of his 100 patients died of the operation and its complications, though from what cause he does not say.

Finally, the operative mortality for the 265 cases at the National Hospital is recorded by Tooth as 53.3 per cent., but as I have pointed out and as he himself emphasizes, these figures do not actually convey the impression which they should, for among the cases recorded as fatal are included, to quote from him, "many positive surgical successes, some almost brilliant considering the circumstances, and followed by relief of pain, improvement in sight and mental state, and prolongation of life." It would be illuminating could we have from Horsley or his surgical colleagues an analysis of these same cases from the point of view of the operator. It is possible, however, to gather from Tooth's tables the fact that about 52 cases (20 per cent.) died within a few hours, and 32 (12 per cent.) some days after the operation, making an operative mortality of approximately 32 per cent.[6]

---

[3] Von Eiselsberg and Ranzi: Ueber die chirurgische Behandlung der Hirn- und Rückenmarkstumoren, Verhandl. d. deutsche. Gesellsch. f. Chir., 1913, xxxii, 515-673.

[4] Krause, Fedor: Chirurgie des Gehirns und Rückenmarks, 1911, p. 572.

[5] As a matter of fact I am greatly surprised that in the series of cases recorded from these four clinics there are so comparatively few secondary operations—only 4 in Professor Küttner's 100 cases and only 17 in the 265 cases from the National Hospital (6.4 per cent.)—whereas in our clinic the percentage of secondary operations is much higher (14.6 per cent.), due doubtless to several factors—to the proclivity toward palliative decompression from a desire to postpone radical measures until we are pretty sure of a localizing diagnosis and to the readiness to reoperaate on recurring lesions.

However these operative results are to be interpreted, we must all feel hugely indebted to Dr. Tooth and to Professor von Eiselsberg for their invaluable reports, and it becomes incumbent upon others of us to have similar analysis made and published, with the inclusion of case record abstracts, so that subsequent readers with an interest in the subject may cull from them what they will. On this present occasion I can do little more than Professor Küttner has done, namely, to assemble the bare facts to which I have access as simply as I am able.

My own experience comprises 334 cases in my Baltimore tumor series and 142 cases observed in Boston during the past 18 months since the opening of the Brigham Hospital. The number of cases, therefore, for a period of about ten years approximates that from the National Hospital, where 500 cases were the basis of Tooth's studies, 265 of which were operated upon. Of my series of 470 cases about 350 have been subjected to one or more cranial operations. Without a long investigation, impossible with the data at hand, I cannot give the mortality figures relating to the Baltimore series, which, however, when recorded will be of importance largely from the standpoint of permanence of relief. Out of the Boston series of 142 cases, 37 of which were hypophysial tumors, 136 have been operated upon, and concerning these cases the following facts may be given.

To avoid too great detail the growths will be divided into those of the cerebral (supra tentorial) chamber, including the hypophysial cases, and those of the cerebellar (subtentorial) chamber, the pontine tumors being here included. In the list I have not included as "operations" either callosal punctures for the relief of secondary hydrocephalus or the many ventricular punctures performed for diagnostic purposes. Moreover, operations conducted in two or three stages, though necessitating reanaesthetization are recorded as one procedure. Only when a second operation has been undertaken after a long interval is it recorded as another operation.

A. THE SUPRATENTORIAL LESIONS

1. *Cerebral Tumors.*—Of 55 cases listed as cerebral tumors proper, 48 have been operated upon 55 times as follows: subtemporal decompression for an unlocalizable growth, 13; an osteoplastic exploration combined with a decompression in the presence of an irremovable growth or of negative findings, 18; an osteoplastic exploration with disclosure of the lesion and its partial or total removal, or a cyst evacuation, 24. Four of the 48 patients have suffered operative deaths as follows:

(1) A patient in extremis, with diabetes and in status epilepticus, with rapidly recurring seizures of a focal character: exploration without anesthesia; negative findings: continuance of seizures: death in twenty-four hours: a small subcortical glioma at autopsy.

(2) A fatal hemorrhage from the longitudinal sinus on the attempted removal at a second stage of a large endothelial sarcoma involving bone and sinus: closure: death in one hour. (A prompt transfusion might have saved this patient.)

(3) A fatality a few hours after the extensive removal, for the second time, of a recurrent parietal glioma.

(4) Exploratory craniotomy revealing multiple tuberculomata, with early fatality (7 days).

Strictly speaking only the second and third of these fatalities was precipitated by the operation. In the other two death without operation was imminent, and in this connection it may be noted that four of the unoperated patients in the series died in the hospital soon after admission and before studies preparatory to operation could be made.

2. *Tumors of the Hypophysis or its Neighborhood.*—Owing to a secondary hypophysial involvement, a large number of the basal and interpeduncular tumors have been included in this group, together with the primary pituitary tumefactions, making 37 cases in all. In these 37 cases 42 operations have been performed as follows: subtemporal decompressions, 20; transsphenoidal operations on the sella with decompression, 2, with partial extirpation of the lesions, 15; osteoplastic frontal operations, 5. There have been two deaths:

(1) A fatality from cerebral compression eighteen hours after a transsphenoidal operation, the third operation on this same individual after long intervals.

(2) The removal in toto of an interpeduncular tumor at a second stage by the frontal route.

3. *Pineal Tumors.*—Owing to our interest in matters relating to the ductless glands this small group is recorded separately. There have been four cases, two of them certified by autopsy, the patients dying in the hospital without operation. One of the living cases was explored with negative findings.

B. THE INFRATENTORIAL LESIONS

1. *The Cerebellar Group.*—There have been 32 patients, all but three of whom have been operated upon, and all told there have been 36 operations. All of the procedures have been of the same extensive type, with a "crossbow" incision and a bilateral exposure with posterior removal of the foramen magnum, often combined with a ventricular puncture and occasionally with removal of the arch of the atlas. In only one instance was the operation conducted in two stages. In 10 of the cases the lesion has not been exposed and its situation remains uncertain; in 12 it proved to be intracerebellar; in 7 it was extracerebellar.

There were 18 explorations which were abandoned as decompressions, for in 16 of them either no lesion was disclosed or if disclosed and presumably operable the patient's condition precluded further manipulations (no fatalities), and in the other 3 a large posterior and mesial, and obviously an irremovable tumor, presented itself (all three cases fatal).

There were 17 partial or presumed total extirpations or cyst evacuations, 2 of them cases which had been previously explored, with negative findings, 7 of them cases in which an earlier partial extirpation had been performed. There were two deaths from the operation.

---

[6] A review of the case abstracts leads to the impression that 99 of the fatalities are attributable to the operation (an operative mortality of 37.3 per cent.), whereas 11 others are questionable. There were 17 more or less acute and fatal infections; 14 fatalities associated with a recorded fungating hernia and discharging wound, and a number of cases of like nature without definite details, showing that there were at least 31 cases of fatal sepsis out of the 99 fatalities, making a percentage of about 30 due to this cause.

Thus in the 29 cases subjected to operation there have been 5 fatalities attributable to the operation (a 17 per cent. case mortality and 13 per cent. mortality for the 36 operations). The fatalities may be detailed as follows:

(1) A young girl with profound pressure symptoms and a cerebellar syndrome had a sudden cessation of breathing the night of her admission. Dr. Bagley attempted an emergency decompression without success. At autopsy a large enucleable tumor was found lying between the two cerebellar hemispheres and flattening the medulla.[7]

(2) Exposure of a large mesial posterior vascular tumor: respiratory cessation on the table: autopsy: a vascular glioma flattening the medulla.

(3) Exposure of a pial endothelioma with conditions practically corresponding to those in 1 and 2:[8] early death (8 hours) from respiratory failure.

(4) A young girl first decompressed (Baltimore series) in 1910; subsequently a partial glioma enucleation by another surgeon (1912); return of symptoms, 1914: successful enucleation of a huge glioma occupying most of the subtentorial chamber. Death on sixth day from streptococcus meningitis.[9]

(5) A young boy, first decompressed (Baltimore series) 1910: subsequently in 1912 a partial enucleation of a glioma of the right hemisphere: return of symptoms with bizarre paralyses, 1914: fatal issue two hours after further enucleation of the large recurrent growth: autopsy: gliomatous extension throughout the entire spinal canal and over base of brain.

3. *Pontine Tumors.*—Five cases have been diagnosed as pontine gliomas—one certified by autopsy after some months. Four of the cases have been operated upon without fatality—and, as may be added, with practically no alteration in the condition. In 3 a subtemporal decompression, and in one a suboccipital exploration, was performed.

C. THE PSEUDO-TUMORS

At present 23 cases are recorded under this diagnosis, and of this number 11 have been operated upon owing to pressure phenomena. Two or three cases originally so grouped have since been shifted to the true tumor list (in one a glioma was disclosed at autopsy, in two others a glioma was found at a second operation). A few others have been removed from this group, as a late examination has shown an abscess or vascular disease, or cerebral lues, or a meningitis serosa, which simulated tumor. A number of other cases not operated upon as yet will doubtless in time come to operation. Hence this particular group is difficult to handle, and probably "questionable" rather than "pseudo" would be a better group designation.

There have been no fatalities in this group, in which there have been 4 exploratory craniotomies combined with a subtemporal decompression, 4 subtemporal decompressions, and 3 suboccipital explorations and decompressions.

A summary of these cases may be tabulated as follows, showing a case mortality for the 130 patients operated upon of 8.4 per cent. and the operative mortality for the 149 operations of 7.3 per cent.

SUMMARY OF CASES

	Cases Observed	Operated Cases	Times Operated	Operative Fatalities
Supratetorial cases	55	48	55	4
Hypophysial cases	37+	37	42	2
Pineal cases	4	1	1	0
Cerebellar cases	32	29	36	5
Pontine cases	5	4	4	0
Pseudo-tumors	23	11	11	0
	156	130	149	11

The following assemblage of the 149 individual operative procedures for the entire series may be given.

Subtemporal decompressions, 41 (no fatality).

Osteoplastic craniotomies combined with cerebral decompression, 28 (3 fatalities).

Osteoplastic craniotomy with attempted partial or total removal of the tumor 24 (2 fatalities).

Transsphenoidal operations for hypophysial tumor, 17 (1 fatality).

Suboccipital exploration and decompression, 22 (3 fatalities).

Suboccipital operations with attempted partial or total removal of the lesion, 17 (2 fatalities).

In this group of 130 surgically treated cases the 70 certified lesions have been as follows. Glioma and gliomatous cyst, 27 (cerebral 18, cerebellar 9); endothelioma, 7 (cerebral, 2, cerebellar, 5); angioma (endothelial ?), 2; sarcoma, 1; carcinoma (metastatic), 1; syphiloma, 4; tuberculoma, 4; osteoma, 1; echinococcus, 1; adenoma, 17 (hypophysial, 15, pineal, 2); interpeduncular mixed tumors, 5. It may be added that a few of the lesions which are histologically difficult to classify have been put with the gliomas, on the basis of the finding of a few glioma fibrils.

In order to show the type of cases we have included and of those we have excluded from the operative fatalities I may mention the 3 tuberculous cases. In one of them, recorded as a fatality, the patient was in extremis, with pulmonary tuberculosis, but owing to his intense discomforts an operation was undertaken —an exploratory craniotomy which better judgment would have made a simple decompression. There was great tension of the hemisphere with extensive tuberculosis radiating from a large tuberculoma—an inoperable condition. He died 7 days after the operation. The two other patients, not included with the operative fatalities though both of them subsequently died, were children. In one of them a simple suboccipital decompression was performed with no apparent change in the condition. A few weeks later he was removed to his home, where death occurred shortly afterwards, and a fragmentary autopsy disclosed a cerebellar tubercle. The other, a child of 3, died in the hospital three months after a successful extirpation of two large tuberculomas from the left cerebellar hemisphere. The postoperative conditions were perfect, with great improvement in the child's condition, but after a month's time a progressive hemiplegia set in, with ultimate death and the disclosure at autopsy of a third tubercle in the left crus cerebri and a basilar meningitis.

Cases of this sort, I am aware, if placed among the surgical fatalities would considerably increase their number, but even if they are to be included I nevertheless feel that the recorded mortality percentages from foreign clinics convey an absolutely erroneous idea of the immediate surgical risks of brain tumor operations. I can hardly imagine an optimism sufficient to carry a surgeon into a class of work in which one out of every two or three patients dies obviously from one's intervention, well intentioned though it may be. It is possible that we have estimated our percentages on a different basis, for otherwise I can hardly account for the discrepancy between the figures which I have given and those of the major foreign clinics where these operations in considerable number are undertaken. Still another explanation lies in the fact that these Brigham Hospital figures represent an experience of only the past 18 months, whereas the figures from Breslau, London, Berlin and Vienna comprise the experiences, in some cases, of a decade and reach back to a time when for many reasons the expectancy of life after such procedures was doubtless less than it is today.

---

[7] The case might justifiably not be included among the operative fatalities. However, I have once succeeded in saving a patient under similar circumstances, with resumption of spontaneous breathing on the operating table after evacuation of a cerebellar cyst, *45 minutes after the sudden cessation of respiration in the ward!*

[8] It is unusual to meet with three cases like the above in a small series. But for their situation the growths would have been enucleable, and though lying largely within the cerebellum they were in a strict sense probably all extracerebellar.

[9] I grieve to record this my single fatality from meningitis in the entire series. It was a long performance and the operating room orderly who held the head during the preliminary preparations was ill and was confined to bed the following day with a streptococcus throat and scarlet fever.

However this may be, I nevertheless feel that the effects of concentration of work show themselves in our results, which depend so greatly on such details as perfection of anaesthesia, scrupulous technique, ample expenditure of time, painstaking closure of wounds without drainage, and a multitude of other elements, which so many operators impatiently regard as trivialities. Certainly infections cannot be attributed to the intervention of the devil but must be laid at the surgeon's door. We have had no example of wound infection of any kind with the single exception of the wildfire case of meningitis which I have recorded, and such a thing as a fungus cerebri after an operation is unknown in our experience, owing I think to the careful closure of the galea with interrupted silk sutures which is invariably practiced, for on this buried layer the strength of the wound depends, the skin sutures being removed usually in 48 hours. Krause has the enviable record of no instance of meningitis in his series, whereas a great opportunity for improvement is shown by the 10.5 per cent. mortality from meningitis in the Vienna series and the still higher percentage (11.7 per cent.) of deaths recorded as due to sepsis at the National Hospital.

After all this wearisome and embarrassing comparison of operative statistics I may be permitted to return to the theme of my opening paragraphs, where it was pointed out that the discussion of this whole subject would cover too large a ground, including as it does all tumors of all kinds in all parts of the cranial chamber. The time has come when for proper advance we may well devote our analytical studies of operative results to specific types of lesions in specific localities, as, for example, the hypophysial tumors, the cerebello-pontine lesions, the cerebellar gliomas, the endothelial tumors, tumors of a metastatic or infectious origin, and so on. This I have already attempted to do, in a paper printed in this journal,[10] with the hypophysial cases, which henceforth may well be excluded from the "brain tumor" series. Only in this way may we arrive at a better understanding of what actually are the probabilities of recovery from an operation of a given type upon a particular lesion.

Confused as one may remain in regard to the results from this or that clinic when the entire subject is considered, when it is brought down to a single topic a comparison is much clearer. Let us, in illustration, consider for a moment the cerebello-pontine (acoustic or lateral recess) tumors. Long ere this the general principles of attack upon these supposedly enucleable and easily diagnosed tumors should have been a matter of common knowledge. But there is no agreement as to whether there should be one or two stages, a bilateral or a unilateral exposure, an osteoplastic operation or otherwise, an approach through or to the side of the cerebellum, an attempt at a total enucleation or not, drainage of the wound or otherwise, and so on. It is a procedure accredited with a very high mortality. In 24 such operations Krause has had 20 fatalities; von Eiselsberg in 17 cases lost 2 after a first-stage, and of the remaining 15, 10 of the 11 in which there was an attempted tumor removal died of shock; 24 of the 36 cases operated upon at the National Hospital died from the effects of the operation (9 after a decompression, 15 after a partial removal, 5 of sepsis).

This gives for the 77 cases in the three clinics a 72.7 per cent. average mortality, which is of course appalling for an operation upon a lesion possibly the easiest to localize of all intracranial tumors; and as Tooth says, the only hope of lowering the mortality in these cases is by a modification of the surgical procedure. The direction of this modification lies, I think, in performing these suboccipital operations with a bilateral exposure and in one instead of two stages; in carrying through the elaborate approach to the lesion with complete haemostasis, even though it means a two hours' labor; in lowering tension by an occipital puncture of the lateral cerebral ventricle; in removing the posterior half of the foramen magnum, and possibly, in case of great cerebellar herniation through the foramen, the arch of the atlas as well; in being content, in view of the obvious impossibility of a total enucleation of the growth, entangled as it is in the nerves and vessels of the lateral recess, with the mere splitting of the comparatively non-vascular lesion with subsequent scooping out, on each side, of as much tumor tissue as possible, leaving its capsule in place; in accurate closure of the wound in layers without drainage; in leaving the patient in the face-down position on the table if necessary for hours should there be any question of threatened respiratory difficulty; in the willingness to give an entire morning of three hours at least to such an undertaking.

My own series, going back ten years, contains 13 of these cases which have been certified by operative exposure and 17 cases in which the diagnosis of a cerebello-pontine tumor was made but in which the operation was concluded as a decompression, short of laying bare the lesion. It is possible that there may be still other unrecognized cases, but these are possibly offset by others again in which a previous diagnosis of a cerebello-pontine lesion has been proved erroneous by the finding of an intracerebellar lesion at a second operation, I having had several experiences of this kind. None of the 17 cases with a decompression alone have been fatal. There have been 4 fatalities in the 15 operations on the 13 patients with a certified lesion; one of them from a pneumonia following my first operation of the kind—a sorry attempt ten years ago—and the three others from bulbar symptoms after more or less extensive fragmentary enucleations. Though the series is admittedly small, this gives a mortality for the 13 certified cases of about 30 per cent., and if the suspected cases are included, of only 13 per cent. Indeed, we do not share the view, which seems to be held in other clinics, in regard to the extreme surgical risks of subtentorial operations in general, though admittedly they are greater than in other intracranial procedures. Still, I realize fully that we may be riding to a fall, and that our cases may have been brought to us earlier and thus the operations on the average have thus far been 50 per cent. easier and less hazardous than in the other clinics.

---

[10] Surgical Experiences with Pituitary Diseases. The Weir Mitchell Lecture, The Journal A. M. A., Oct. 31, 1914, p. 1515.

Unquestionably the general results of the efforts on all sides to give relief by surgical measures to individuals suffering from tumors of the brain are perceptibly improving and the mortality percentage is being constantly lowered. There are two underlying reasons for this. One is the great improvement in technical methods of performing these admittedly difficult operations since the days when von Bergmann gave his pronouncement of their hopelessness except in the case of tumors of the paracentral zone. Disastrous have been the attempts to apply to intracranial procedures the same rough surgical methods which the abdominal viscera and their coverings tolerate but against which the central nervous tissues rebel. Surgical manipulations of an entirely different order from those permissible elsewhere in the body are essential to success in intracranial performances, and they demand special training.

A second and equally important reason for the recognized improvement in neurological operations concerns the changed attitude of the surgeon toward the subject, for as I have frequently emphasized he should be able to make his own neurological examination. No notable advance was ever made along any line of manipulative handicraft so long as the operator remained merely the tool to execute a procedure directed and conceived by another who alone assumed the responsibility of a diagnosis. The neurologist has been as quick to appreciate this as has the internist in the case of surgical performances for the disorders of the abdominal organs, which were once his special domain.

There is a prevalent view, due undoubtedly to the sorry experiences of the past and the bungling results of the untrained at the present time, that all of these operations for brain tumor should be undertaken only as a last resort when the clinical features of the case have become outspoken and the sorry plight of the victim can hardly be made worse, whatever the outcome of an operation. History repeats itself. There was a similar chapter in the story of the appendix, the gall-bladder, the pylorus and the thyroid, to give only some very modern instances. Still, if an intracranial exploration is attended by extraordinary risks this is indeed a justifiable view; so that the first thing that one must be able to assure his patient, his patient's councilors and himself, is that there is no great hazard in an exploration and a probability of improvement even when no tumor is revealed, or one which no attempt should be made to remove. This, indeed, is more than can be said of most of the purely exploratory operations performed for new growths involving the abdominal organs, for at best the closure of a laparotomy wound, in the face of an inoperable lesion, leaves the patient's condition unaltered, whereas a properly conducted craniectomy is in itself often beneficial.

There are certain things which make this assurance possible. Far from the least important is the smooth administration of the anaesthetic by one who is specially trained for its administrations in these difficult cases. Again, these procedures should never be attempted in unaccustomed surroundings: it is far safer to transport an ill patient to a well organized surgical machine than it is to operate awkwardly with a makeshift team in unaccustomed surroundings. The technical steps are delicate; the performances are time-consuming; wounds must be left dry before closure and closure must be without drainage; patients if in a critical condition may needs remain unmoved on the operating table for many hours; a donor should be in readiness for transfusion should there be an excessive loss of blood; absolute perfection of wound handling and wound closure must be observed, with early removal of sutures, for in many cases of tumor removal two, and even three or four, stages must be anticipated. Then even at home one cannot justifiably crowd difficult and responsible operations of this type into a busy operating schedule, even if they could be done with greater speed than we at least feel justified in making. Some of our neurological friends have long placed more emphasis on speed than on care, and indeed from the onlookers' seats these detailed performances must often seem utterly tedious, but it is a familiar adage that the grandstand is a poor place from which to conduct the play.

I have amplified this discussion to an unexpected and possibly unnecessary length in my attempt to register the conviction that to group together all the operations for all tumors which arise anywhere in the cranial chamber and to consider percentages gained by such a process, is largely a waste of time and a possible abuse of figures. Unquestionably the time has come for us to concentrate upon individual lesions in individual situations if, through comparative studies, we are to increase our technical facilities and improve our mortality results.

Specialization with some knowledge of neurology, skilled assistance—for intracranial operations are not star performances—familiarity with the safe and respectful handling of the central nervous tissues, which is best acquired by the experiences of the experimental laboratory, and painstaking, scrupulous technique, are the chief elements of success. An observance of these things will not make more tumors accessible, but it will permit the removal of those that are accessible to be more often accomplished and render those that are not, capable in a larger percentage of cases of being safely palliated.

The Peter Bent Brigham Hospital.

The Unbalanced Antivaccinationists.—There is something about the antivaccination propaganda which appeals with irresistible force to a certain type of unbalanced mind. Of every ten letters written to the *Journal* against vaccination, six belong to a well-marked type. They bristle with adjectives, mostly uncomplimentary ones. They repeat certain phrases over and over again. They overflow with statistics of things that never happened. They impute the most evil motives to all who differ from their pet "ism." Their argument, if present at all, runs in a circle: "I hate vaccination because it is poison, and I know it is poison because I hate it." They show an utter disregard of facts, they ignore the plainest evidence that conflicts with their views, and put absolute faith in the wildest, craziest tales that agree with their preconceived notions. The writers of these epistles may not be insane, doubtless are not, in the usual sense of the word. Neither are they persons whom a thoughtful citizen would choose as trustees of his estate or guardians of his children. They do not stand alone in their opposition to vaccination—if they did, the task of sanitary officers would be easier than it is—but they do furnish a large part of the misdirected energy whose sole effect is to perpetuate a loathsome and dangerous plague.—Chicago *Daily Journal.*

THREE CASES OF EXTRAPERITONEAL CESAREAN SECTION*

GEORGE GELLHORN, M.D.

ST. LOUIS

Probably none of our operative procedures has had a more rapid growth and development than cesarean section. Within the brief span of ten years it has undergone a wide extension of its scope and radical changes in its technic. It was formerly applied only as a measure of last resort and was altogether limited to cases of dystocia due to extreme contraction of the pelvis. When the suggestion was first made to perform cesarean section in placenta praevia, it provoked rather strong opposition (Ehrenfest[1]), but the indication has, of late, been upheld by many writers (Bumm, Kroenig, Nagel,[2] Kohlmann[3] and others). The therapy of eclampsia is still a mooted question, yet those who advocate active intervention and include cesarean section among the means of quickly evacuating the uterus are by no means less numerous than the adherents of an expectant mode of treatment (Peterson[4]). Craniotomy has properly been denounced as an unjustifiable procedure except in rare instances, and in proportion cesarean section has been brought to the fore. The induction of premature labor in cases of moderate contraction has, in hospital and clinical practice at least, shown considerable disadvantage and the future fate of the infants has been so far from satisfactory that cesarean section has been advocated as a preferable alternative. Then, we find scattered in literature occasional indications for cesarean section, such as premature separation of the placenta (Küttner[5]), uncompensated heart disease (Kreiss[6], Barris[7]), edema and varicosities of the vulva (Brunet[8]), prolapse of the parturient uterus (Warren[9]), complication with ovarian cyst (Broadhead[10]). And finally, it has been claimed quite recently (Newell[11]) that many modern women, weakened as they are by the deteriorating influence of hypercivilization, can but badly stand the strain even of a normal labor and have to pay dearly for the privilege of motherhood by a prolonged, if not lifelong, invalidism, but that such patients will undergo and recuperate rapidly from a cesarean section.

This amazing multitude of new indications can be explained in part by the fact that, since Saenger, in 1882, presented us with the technic of the "classical" cesarean section, modern antisepsis and asepsis have steadily reduced the mortality of this operation until it reached its low water mark of 12 per cent. in 1904 (Nicholson[12]). In selected cases the mortality has sunk as low as 2 per cent. (Boyd[13]), and in the hands of particularly experienced operators has become still further diminished to a negligible quantity.

But where there is much light there must be shadow as well, and as the number of cesarean sections increased, certain undesirable after-effects became apparent. The unsightly abdominal scar with its ever-present tendency toward hernia was, perhaps, the least untoward sequel. Much more serious was the frequent, nay, the almost constant, occurrence of postoperative adhesions, the unintentional ventrofixation of the uterus, with its train of annoying symptoms, the possibility of ensuing miscarriages, or the danger in future deliveries from the pathologic immobilization of the uterus.

Thus it was that a number of modifications came into being, among which the "high" incision of Davis[14] has more recently become popular, because it was claimed that adhesions could thereby be prevented.

The classical cesarean section and its modifications had this premise in common, that the case to be operated on had to be "clean," that is, the membranes had to be intact or but quite recently ruptured and previous examinations and attempts at delivery had to be strictly avoided. Now and then fortune may favor with impunity one who ignores these precautions,[15] but, as a rule, trespassing is quickly followed by infection and death.

There still remained, then, a large number of so-called "unclean" cases in which infection was already established or the precautions enumerated had not been observed, or else "suspected" cases in which there was some doubt as to the proper preoperative handling. It was for just such cases that Frank of Cologne, in 1907, invented a new method of cesarean section called "extraperitoneal," which was in all essentials identical with an operation originated by Thomas of New York in 1870, but since fallen into oblivion. The principle of the new method was to make the incision into the lower uterine segment instead of into the fundus, and to exclude carefully the operative field from the rest of the peritoneal cavity. That Frank's procedure filled a long-felt want and was published at the psychologic moment was shown by the stormy enthusiasm it kindled abroad and the large number of more or less radical modifications. An interesting and exhaustive résumé of the development of extraperitoneal cesarean section has been written recently by Nicholson.[12] For us it may suffice to say that extraperitoneal cesarean section did not fulfil the hopes originally placed in the new procedure. Patients already infected could not be saved by it. Brilliant results, however, were obtained when the operation was performed on "suspected" patients, and even more so when it was employed in aseptic cases.

It will not be necessary to concern ourselves in detail with the numerous modifications of technic. The bewildering particulars of the various procedures are of interest more to the specialist. To a general audience, however, it must be of importance to realize that these newer operations offer advantages far in advance of the more generally known methods of cesarean section. This, I trust, will become apparent from a description of the three cases of extraperitoneal cesarean section which I have had occasion to perform in the last eight months.

CASE REPORTS

Case 1.—Mrs. J. L., 35 years old, had her first confinement three years ago. After a long labor a dead child was extracted with forceps. A year later she had a miscarriage.

---

[15] I have reported[15] a case of cesarean section performed elsewhere on a dead child after numerous fruitless attempts with forceps had been made in the house of the patient. This woman recovered from the operation but had a serious dystocia at her next confinement.

[16] Gellhorn, G.: Mo. State Med. Jour., 1910, vi, 632.

Jan. 27, 1914, she again was in labor at full term. She had had moderately severe contractions for about forty-eight hours and very strong and frequent pains for about eight hours. At midnight I was called by the two physicians in attendance to perform cesarean section. The membranes had ruptured a considerable time previously, and repeated vaginal examinations had been made *without rubber gloves*.

I found the patient of medium height, with a moderate kyphoscoliosis and a generally contracted pelvis of mild degree (Sp. 22½ cm.; Cr. 26½ cm.; Conj. ext. 19 cm.). The fetal heart-beats were on the left side near the flank. In the upper part of the vagina there was an annular constriction due to scar tissue, the result of her first delivery. The fetal head could hardly be reached from below, nor could it be impressed into the pelvis. The child was obviously very large, to judge from the size of the abdomen. The uterine contractions were becoming weaker but were still frequent.

The indications for a cesarean section were, then, clearly given: a contracted pelvis, a large head in occipitoposterior position, freely movable above the pelvis in spite of fifty-four hours of incessant contractions; secondary inertia; and the history of former dystocia.

It was equally clear, however, that any intraperitoneal cesarean section was contraindicated, for not only had the membranes been ruptured for a considerable space of time, but repeated examinations had been made with ungloved hands, and, perhaps, without the most strict observance of antiseptic precautions. There was, as yet, no fever, but the possibility of an infection, however mild, pointed to the necessity of choosing the extraperitoneal route for the cesarean section.

The steps of the operation were as follows: The patient was catheterized and narcotized with ether. One cubic centimeter of pituitary extract was injected intramuscularly. In extreme Trendelenburg position a midline incision was made from the symphysis to within 1½ inches of the umbilicus. The lower uterine segment distended by the child's head, presented. The peritoneum, which, in pregnancy, is only loosely attached to the lower uterine segment, was lifted with a tissue forceps at its highest point which corresponded to the upper end of the abdominal incision, and transversely incised a distance of about 2 inches. The peritoneum, and with it the bladder, was then gently pushed toward the symphysis with the finger or a sponge in the fashion of a hysterectomy until the firmer connection between bladder and cervix called a halt. The engorged veins at the base of the bladder now became visible and were protected from injury by a large retractor which at the same time held the bladder against the symphysis. A denuded oval with a diameter of about 5 inches thus resulted on the anterior surface of the lower uterine segment. The parietal peritoneum was now stitched to the edges of this denuded oval by means of a continuous catgut (or linen) suture and thereby a complete closure of the abdominal cavity was produced which rendered the rest of the operation absolutely extraperitoneal. Then followed the incision through the lower uterine segment within the entire extent of the denudation and the opening of the amniotic cavity. The child's face was rotated into the uterine incision by placing a finger into the child's mouth. While an assistant held the face in this position, a forceps was applied with the concavity of the blades toward the symphysis and the head gently extracted. The body followed immediately. The child, a female, weighing 10¼ pounds, cried at once. Placenta and membranes were removed instantly and a hypodermic injection of ergot was given. The uterine incision was closed by through and through interrupted sutures of chromic (or tanned) catgut No. 2 and a superficial running suture of finer catgut. The denuded area was cleansed with hot saline solution and dried with sponges. The uterus contracted promptly and there was practically no bleeding throughout the operation. The continuous stitch between parietal and visceral peritoneum around the denuded area was now removed, the bladder peritoneum pulled over the entire wound and sewed on the anterior surface of the uterus a trifle above its original insertion by means of three or four interrupted (or continuous) sutures. The operation was concluded by closing the abdominal incision in the usual way.

The patient went through an undisturbed and afebrile puerperium and left the hospital within two and a half weeks.

Oct. 3, 1914, the patient was in the best of health. There was a strong linear scar. The uterus was of normal size, position and mobility. The child was thriving.

CASE 2.—Mrs. P. H., 25 years old, colored, a dwarf with coxa vara and a deformed knee-joint. Pelvic measurements were as follows: Sp. 24½; Cr. 25; Tr. 33½; Conj. ext. 21½. The pelvis was of the Naegele type of oblique contraction: the anteroposterior diameter lengthened, the transverse diameter asymmetrically shortened due to the fact that the entire left pelvic wall was pushed inward. The child was in L. O. A. position. Although natural delivery seemed quite improbable, it was decided to give the patient the test of labor. Consequently, when labor commenced on June 6, 1914, 6 drops of pituitary extract were injected in order to intensify the contractions. Vaginal examinations had carefully been avoided for several weeks. After twelve hours the head was still freely movable above the pelvis and cesarean section clearly indicated.

The technic of the operation was identical with that employed in the first case, except that it was performed in spinal anesthesia. A male child, weighing 5 pounds 1 ounce and crying at once, was delivered. There was no bleeding during the operation. Convalescence was rapid and undisturbed. Three months later the patient was demonstrated before a number of physicians. The abdominal scar was firm, the uterus small, in normal position. Child well.

CASE 3.—Mrs. A. J., 22 years old, primipara, has always been delicate and poorly nourished. Systolic blood-pressure ranged between 88 and 102 throughout pregnancy. Pelvic measurements: Sp. 20 ½; Cr. 24½; Tr. 28½; Conj. ext. 18½. Aug. 27, 1914, she had been in labor at full term for the past thirty-eight hours. Contractions were regular but only moderately strong in spite of repeated injections of small doses of pituitary extract. The fetal head remained movable above the pelvis. The cervix was ½ inch in length and open for two fingers. The patient showed signs of exhaustion.

The indications for surgical delivery in this case were as follows: Generally contracted pelvis of moderate degree; a large child; primary inertia; delicate and exhausted mother. The technic of the operation coincided in all details with that of Case 1. A female child of 7 pounds 6 ounces, crying at once, was delivered. Recovery was rapid.

Oct. 23, 1914, the patient was perfectly well. Strong linear scar. Uterus of normal size, position and mobility. Child well.

The technic employed in the three foregoing cases has been slightly modified from the one depicted by Kroenig[17] and originated by Veit and Fromme. As appears from the description, it is strictly speaking a transperitoneal method. The parietal peritoneum is first incised, then the visceral peritoneum is pushed off the lower uterine segment and, finally, by stitching the parietal peritoneum to the uterus, the free abdominal cavity is excluded and the operation rendered extraperitoneal. Of the twenty different methods of extraperitoneal cesarean section enumerated by Nicholson, this one appeals to me most strongly because of its simplicity, safety and elegance of procedure. Its superiority over the classical cesarean section, with or without lifting the uterus from the abdominal cavity, is at once apparent.

In the classical cesarean section we have, as pointed out above, an enormous scar with a proportionately increased possibility of hernia; an almost positive certainty of adhesions between uterus and abdominal wall, which carries with it more or less annoying late symptoms and may be a source of danger in future pregnancies; copious bleeding during the operation; escape of amniotic fluid and meconium into the peritoneal cavity during the section and possibly leakage of wound fluid later on due to the contractions of the uterus.

---

[17] Kroenig, B.: Doederlein und Kroenig, Operative Gynäkologie, 1912, Ed. 2.

Some of these obvious drawbacks also accompany the "high" cesarean section of Davis, for the profuse bleeding and the escape of amniotic fluid is common to both types.

The chief claim of the high incision is the prevention of adhesions and while such prevention seems plausible enough from a theoretical point of view, actual experience points the other way. Only recently Studdiford[18] demonstrated a uterus with extensive adhesions due to a high cesarean section, and a number of similar observations were recorded by speakers in the discussion following. It is this occurrence of adhesions which makes or mars the result of any abdominal operation. Only he who has had such adhesions himself or has tried in vain to cure them in others will fully appreciate the importance of prophylaxis. Indeed, it seems to me that at present the prevention of adhesions is at once the most important and difficult problem that confronts the abdominal surgeon.

For this reason alone, if for no other, the extraperitoneal cesarean section, and particularly the special technic employed and described in my three cases, recommends itself in preference to either the classical or the high cesarean section. Postoperative adhesions are inconceivable after the extraperitoneal method. The temporary protection of the abdominal cavity by whipping the parietal peritoneum onto the uterus prevents the escape of even the smallest amount of amniotic fluid which eventually might irritate the serous surfaces and give rise to adhesions.

After the operation the bladder peritoneum completely covers the field of operation, and even the three or four sutures which fasten the vesical to the uterine peritoneum disappear altogether from view owing to the continued contractions of the uterus. Thus an unbroken peritoneal surface is left behind, which can neither adhere to the parietal peritoneum (provided the latter has also been closed with proper precautions), nor can it lead to intestinal adhesions.

The afebrile course of the recovery and the perfect well-being of my patients at present still further corroborate this statement.

Other advantages of the extraperitoneal cesarean section are equally obvious. The description of the *modus operandi* may perhaps sound complicated; the actual operation is the reverse. There is a simplicity about it which must needs appeal to the surgical mind. Accustomed as we are to the abundant bleeding during the classical or high cesarean section, the almost total absence of bleeding from the incision in the lower uterine segment is striking. Nor is there any bleeding from the stitch holes around the denuded area.

We know, as a general principle, that any wound in order to unite firmly must be put at rest, but this desideratum is not feasible in the classical or high cesarean section, because the incision has been made through the contractile part of the uterine muscle, which continues contracting for days; whereas in the lower uterine segment such periodical disturbance of firm union does not obtain. These physiologic conditions not only render an exact adaptation of the cut edges in extraperitoneal cesarean section easier than in either of the other two methods, but they also safeguard against the possibility that wound secretions may be squeezed out into the peritoneal cavity.

On the other hand, does not this very thinness of the wall and comparative lack of contractile muscle fibers favor rupture of the scar during a future pregnancy or delivery? This objection which, theoretically, seems well founded, has deterred me for years from adopting the extraperitoneal cesarean section. Practical experience, however, has not supported such anticipation. Nicholson, in his thorough study of the literature, concludes that, "in so far as we may judge by the statistics at present available, there is at least no marked tendency to rupture of the old scar or other difficulties in future pregnancies."

The scar after extraperitoneal cesarean section is practically identical with that of a vaginal cesarean section and we know that the latter does not predispose to rupture. Within the last year I had occasion to deliver two women on whom I had performed vaginal cesarean section some years previously. Both deliveries were normal, exceptionally rapid, and without any cervical lacerations. Similar observations have been made by others.

That injuries of the bladder or traumatism to the vesical plexuses can be easily enough avoided, appears from the description. As a matter of fact, I am not aware that any such complications have been recorded.

There is no need to fear that the pelvic connective tissue will become infected if only the operation itself has been strictly aseptic. Neither need we feel concerned lest the available space prove too small for our manipulations and the incision tear further during the extraction of the child. Such an objection is largely theoretical if we remember that the incision through the lower uterine segment measures about 5 inches.

There is only one condition in which the extraperitoneal does not offer advantages over the intraperitoneal method, and that is in the placenta praevia. Here an incision through the lower uterine segment would open the enormously dilated blood sinuses, the inundation with blood would render orientation difficult, the lack of contractile fibers militate against prompt checking of hemorrhage, and the friability of the tissues favor tearing and prevent accurate adaptation.

With this single exception, the extraperitoneal method not only possesses all the advantages of the ordinary cesarean section and its modifications, but so far as our present experience goes, surpasses it in safety and freedom from postoperative complications.

It seems strange, therefore, that the newer method has found but scant recognition in this country. For aside from my three cases, there has been reported in all but eighteen others—one operated on by Kelly,[12] another by Druskin[19] and sixteen by Hirst.[20] This last author, who employs a method similar to that used in my cases, expresses himself enthusiastically and gives the extraperitoneal method preference in the majority of instances.

A few more cases were put on record in the discussion on Hirst's paper just referred to. Growing familiarity with the technic will no doubt remove quickly the bars which in the past have prevented the general adoption of extraperitoneal cesarean section.

JOSEPH V. KLAUDER, M.D.
PHILADELPHIA

The clinical history of syphilis, admittedly one of the most protean of all diseases, is in the process of being rewritten, and when the chapters are relatively complete it will be found that we are indebted rather to the laboratory worker than either the internist or neurologist for our more complete knowledge. It was at one time supposed that syphilis of the nervous system was a late manifestation of the disease, and this statement is generally true from the clinical point of view. Precocious syphilis was the term employed by Gowers for those cases in which patients manifest organic nervous phenomena within a year from the appearance of the primary lesion. For many years it has been recognized as a possibility, and cases have been reported by Gowers, Fournier, Oppenheim, Nonne and others, including an instance furnished by Gregory and Karpas of a case of cerebral syphilis occurring six months after the development of the primary lesion.

In going over some of the patients and records in the hospital at the naval home in Philadelphia, with Dr. Stokes, formerly surgeon-general of the U. S. Navy, I was struck with the greater virulence of the disease in general and the serious and occasionally early involvement of the nervous system occurring in sailors who had contracted the disease in the Orient. It is solely from the clinical point of view, however, that we of to-day are justified in regarding syphilis of the nervous system as among the later phases of the activity of the treponema. Soon after the use of salvarsan became general, considerable discussion arose as to the part it apparently played in causing involvement of various cranial nerves and other more or less pronounced nervous symptoms. Previously free, involvement became manifest within a few hours or days following an injection of the drug. Routine study of the cerebrospinal fluid from luetic patients revealed to Dreyfus that about 80 per cent. of late primary and early secondary cases show distinctive pathologic changes in the spinal fluid (cytologic increase or increase in protein content and more rarely a positive Wassermann). Thus, the explanation of the preceding, essentially a Herxheimer reaction, local or diffuse, depends on distribution of the treponemas, and is due to liberation of toxins resulting from the lytic action of salvarsan on the parasite.

This carries with it the thought, first, that all initial doses should be small, and secondly, if symptoms of involvement of the nervous system occur, it is not necessarily a contra-indication to the further use of the remedy, but rather the reverse, though in small doses. Even the few early cases which we have felt justified in submitting as illustrative, show well the pathologic changes in the spinal fluid and there is absolutely no doubt from the point of view of the serologist, that the vast majority of luetics, from the date of the primary infection, are essentially candidates for syphilis of the nervous system. Though they may not present a single symptom, the treponemas invade all parts of the body within a day or two at most from the time of infection. Neisser succeeded in inoculating animals with blood taken from monkeys five days after the original infection and with splenic pulp taken on the twelfth day. Hoffmann has shown that monkeys may be infected by using the blood from a human in the secondary stage, and that under such circumstances the incubation stage in the monkey is shortened. Infection successively passaged through a series of animals increases the virulence of the infection and shortens the incubation period. Flügel recovered the treponema from the blood of a woman with a secondary, maculopapular eruption. Indeed, it is probable that the eruption is in the nature of a parasitic embolism similar to the rose spots of typhoid fever, which are mycotic, congested, capillary loops. Veillon and Girard selected a typical maculopapule and excised it on the third day after it appeared. The capillaries were dilated and congested with an early, perivascular, lymphocytic infiltration, and treponemas were found, by the silver method, in and about the capillaries. Neisser, Buschke, Levaditi, Tomasczewski, Noguchi and others have found the parasite in tertiary lesions of the skin and various organs including the nervous tissue, either by direct staining methods or by inoculation into animals. Von Zeissl found records of more than 150 cases of facial paralysis, deafness or retinitis occurring within one year of the period of original infection. Thus it is evident that every stage of the disease is potentially infective; the possibility of transmission, however, becoming less in direct proportion to the elapsed time since the original infection.

Two points in connection with the primary infec-lesion, the knowledge that syphilis may be contracted without the development of a chancre, and the well-known evanescence of secondaries in some cases, should render us tolerant in our judgment of those from whom no history is obtainable. Jonathan Hutchinson has reported several cases, one in a nurse and several in physicians, in whom the disease followed a punctured wound, the first evidences of actual infection being adenopathy and eruption. This possibility has since been confirmed experimentally. A chancre is only possible when cutaneous or mucous membrane infection occurs. Again, we sometimes see a patient in whom a chancre has developed, often atypical, to be sure, who admits exposure months or even a longer period in the past, but who denies recent infection. Keogh, in 1911, called attention to the fact that, in relapses occurring even at long periods after salvarsan has been given, whether the Wassermann be positive or negative at the time of the relapse, the clinical picture is more or less a replica of the condition presented at the time the patient first sought treatment. Thus, if treatment is given in the primary stage, a relapse is often manifested as a chancre, secondary stage—secondaries. Keogh regards this as a true latency, unlike the apparent latency of cases treated with mercury, which, as a rule, assume a far more advanced type in the relapse.

Briefly, then, the present concept of syphilis is that, in its earlier stages, it is a septicemia with more or less involvement of the nervous structures and coverings from the beginning. In the course of time, for some unknown reason, special predilection is manifested for some particular organ or tissue, *after a period of* apparent latency which only serologic study will reveal. In some instances, indeed, the latency is so well concealed that only a provocative Wassermann, as first suggested by Gennerich and almost simultaneously by Milian, will reveal it. This test is practically a Herxheimer reaction and proves the presence of treponemas somewhere in the body, hence their lysis and the subsequent successful application of serologic diagnosis. Recognizing the comparative frequency of early involvement of the central nervous system, as shown by the serologist, *it would seem advisable to* make studies not alone of the serum, but also, in every case of lues or suspected lues, to make routine examination of the spinal fluid, and to control treatment by subsequent studies, and, finally, to determine a cure by *provocative injections governed by complete laboratory* observations. It is not too much to claim that such a plan would in all probability prevent the development of the more destructive forms at present so common among us.

* Read before the Section on Practice of Medicine at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

* Because of lack of space this article is abbreviated in The Journal. The complete article appears in the Transactions of the section and in the authors' reprints. A copy of the latter will be sent by the authors on receipt of a stamped addresed envelope.

As to types of lues, it is only possible to speak in very general terms. Except for the rare cases in which a chancre fails to develop and those in which secondaries are fleeting or suppressed, the most constant and fairly uniform stage is the septicemic or secondary period. Beyond this we may speak of pernicious anemic or other blood dyscrasias, of cardiovascular, visceral, osseous, ulcerative cutaneous, central nervous (including special sense-organs) and congenital types, but each of these groups presents many varieties. Serologically, we are also unable to speak of definite types. We believe, however, *that when a* standard technic is developed, especially with reference to the Wassermann reaction, and particularly when we reach a conclusion as to the proper antigen to use, less criticism will be leveled against its diagnostic value than is unfortunately the case at present. Even under existing conditions, the chief critics are those who possess no laboratory experience. Until such time it might be of value, in reporting laboratory results, to mention the antigen employed and the particular form of complement-deviation test used in the work, and especially the former. Using an alcoholic antigen prepared from fetal syphilitic liver, a sheep hemolytic system and the method as given by Citron, only varying the complementary strength to obtain relative quantitative results instead of using the continental method of a definite 0.1 c.c. of guinea-pig's serum, it will be found that the large majority of late primary cases, and all untreated secondary cases will give a positive serum, and very rarely a secondary will give a positive Wassermann in the spinal fluid. The majority of secondary cases will also show some other spinal fluid change, as increase in protein content or an increase in cell-count, with prompt reduction of Fehling's solution. Latent cases occasionally give negative Wassermann in serum and fluid, with a positive Wassermann in the serum as the rule, though they may give changes in the protein content of the fluid; but in these cases a reaction may be invariably provoked. The majority of non-latent tertiary cases give positive serums and more marked pleocytosis or protein increase and occasionally a positive spinal fluid Wassermann. Of the nervous forms, tabes is the most frequent. A very small number is serologically negative, but these are rare. The majority have a positive serum, a positive Wassermann in spinal fluid, a moderate pleocytosis and a more or less marked Nonne and less often a positive Noguchi. Since we have used spinal fluid in amounts of 0.5, 1.0 and 1.5 c.c., we have rarely had negative Wassermanns. In the cases clinically marked by severe pain, the cell-count is usually higher, and other evidence of inflammation of the root-zones and meninges is shown by marked Nonne or Ross-Jones and Noguchi reactions. A large proportion of this type also gives a positive Wassermann in the spinal fluid. When strong positive Wassermann is obtained in both serum and spinal fluid, in most instances there is a more or less pronounced pleocytosis up to 50 or 60 possibly per cubic millimeter, with protein increase and often a positive Lange (gold solution). These are the least amenable to treatment and are spoken of as Wassermann-fast types, though not by any means invariably so.

The unilateral type of tabes and those cases presenting but one or two symptoms, as pupillary rigidity and Westphal's symptom, present no special serologic type differing from any of the above. There is one clinical phenomenon of great value diagnostically, which occurs in the vast majority of tabetics and one which is *not sought for routinely*, but which furnishes strong collateral proof of the existence of tabes often at a time when very few criteria are manifest. We refer to that which Collier Martin has termed the tabetic sphincter. Digital examination of the rectum reveals *external sphincter paresis. Firm* lateral pressure is painless and results in more or less relaxation of the anus, permitting a good view of the lower part of the rectum. This relaxation may not be overcome for a period from a few seconds to some minutes.

The greater the degree of meningeal involvement the higher the cell-count and the greater the protein content. Hence, in cerebrospinal syphilis, the high count is found except in the purely endarteritic forms. In some of the cerebrospinal cases the serologic picture *closely simulates that of paresis, except that it is far* more amenable to treatment than is paresis. Hence a serologic diagnosis is of value not alone in a diagnostic sense, but also from the prognostic standpoint.

In general paresis *the rule is to find a strongly positive Wassermann in both serum and spinal fluid*, a moderate pleocytosis and a marked protein reaction. Until very late in the course of the disease, the serum is always positive, but in a small proportion of cases the spinal fluid Wassermann may be negative throughout. Paresis frequently falls under the Wassermann-fast group, and in most instances the Lange, gold solution, runs a parallel course with the Wassermann of the spinal fluid. These laboratory results and our *failure to make satisfactory serologic or clinical* impress on the types of lues involving the nervous system, when combined therapy by mouth and intravenously was employed, led us to take up subdural work. We had made attempts to recover phenolsulphonephthalein, methylene blue and formaldehyd from the spinal fluid but without success, after previous administration subcutaneously in the first, by mouth and subcutaneously in the second, and by mouth (hexamethylenamin) in the third instance, and we had never observed an icteric spinal fluid in any case of jaundice. We were, therefore, ready to accept the view that the best if not the only way to reach the nervous tissue is by direct methods. We found, too, that when we used a direct subdural injection of neosalvarsan without a previous intravenous injection, we were able to recover arsenic in the urine in a few hours, showing that absorption had certainly taken place. Tilney, before the New York Neurological Association, reported some experimental evidence along these lines. He used trypan-blue, a vital stain, injecting 0.1 per cent. into cats and allowing them to live for twenty-four hours. At the expiration of that time, when a subdural injection had been given, the dura mater was intensely stained, the brain stained diffusely. The viscera were not stained. Microscopically he found the trabeculae of the pia extending into the brain and cord were stained, also the walls of the blood-vessels. The ganglion-cells and nerve-fibers were not stained. It seemed, therefore, that the dye found its way into the nervous tissue along the trabeculae and by the blood-vessels. Intra-arterial injection caused skin and visceral staining but none in the brain or cord or the meninges. Intravenous injection resulted in staining of the dura, pia and pituitary, though less than by intraspinal injections. Frozen sections showed the cord unstained. Subcutaneous injection resulted similarly to the arterial, the nervous tissues were unstained, but the viscera were stained.

Sicard employed ink by the lumbar subdural route in animals. In from two to four hours he found particles in the cerebellar region and still later in the region of the peduncles and within the ventricles. In from twelve to fourteen hours he found them also in the cortex of the cerebrum. He observed also that substances in solution in the cerebral fluid were removed by osmosis while particulate substances were removed by leukocytic phagocytosis. In spinal anesthesia it is well known that, if the dose be large and the specific gravity of the injected fluid be low, within a brief period, often a matter of a few minutes, both respiratory disturbance and vomiting will occur. We know also that the subdural fluid and that of the ventricles communicate normally through the foramen of Magendie at the apex of the fourth ventricle and through the foramina of Luschka at the outer margins of this same ventricle. Both on anatomic grounds, therefore, and on the basis of experimental evidence we are justified in our belief that better results must ensue in early cases of syphilis of the nervous system if subdural treatment is resorted to; and as many of the cases also have more or less cutaneous, visceral or osseous lues, the combined intravenous and subdural routes seem to be indicated in those whose infection during the earlier period has not been studied and treated in sufficient detail to prevent the more serious manifestations from arising.

To arrive at the approximate dosage of neosalvarsan given subdurally when 12 c.c. of a 40 per cent. solution are employed after an intravenous injection of 0.9 gm., we took the figures of Bischoff, who found the total volume of blood in the bodies of two executed criminals to be 7.1 per cent. and 7.7 per cent. respectively. Thus, to a patient weighing 150 pounds, each cubic centimeter of serum would contain about 0.00017 mg., and 12 c.c. about 0.002 mg. We then employed the Abelin reaction to determine the presence of arsenic in serum and urine. Using dilutions of known strength we obtained the following figures:

1:100	Beautiful red contact ring
1:10000	Reddish ring
1:20000	Brownish ring
1:30000	Brownish ring
1:40000	Brownish ring
1:50000	Very faint brownish ring
1:60000	Negative

We were unable to obtain a reaction in the serum of blood removed in ninety minutes, in any patient treated intravenously, and we have found a negative in one case and weakly positive in another at the end of sixty minutes. In the urine we were unable to recover it after ten hours. After intramuscular injections we did not examine the serum, but in the urine we obtained the reaction in thirty-one and forty-eight hours respectively. Abelin found practically the same results, though in two patients of his series treated intravenously, he obtained the reaction in the urine in seventeen and twenty-two hours. We found the reaction positive in the serum in from ten to fifteen minutes after the intravenous injection was given. The early disappearance of the Abelin reaction led us to take the blood in from thirty to forty-five minutes after the intravenous injection was completed. We have treated nine cases in all, two by the Swift and Ellis alone, two by the direct method alone, and five by combined Swift and Ellis and direct methods. Despite the experience of Wechselmann and Marinesco and more recently the experimental evidence of Swift and Ellis, we determined to try the effect of direct injections without previous intravenous. The maximum dose employed was 0.02 gm. of neosalvarsan, and the minimum 0.006 mg.

In all dosage we found the direct method too irritating. After a total of 11 direct injections, we found that the three paretics suffered the least, two of them having to be catheterized, one during the first twenty-four hours, one only at the end of the third day, and the paretic who had received 0.02 c. gm. and 0.01 c. gm. at different times, had no symptoms at all. Of the cases of taboparesis and tabes, all the direct injections were followed by severe pain, causing retention necessitating the use of the catheter for as much as two weeks and obstinate constipation. The direct injections were given in salt solution to one patient only, while in the others we employed the patients' inactivated serum in salt solution, a 40 per cent. dilution. It is well known that irritative phenomena occur after the Swift and Ellis method, so that if, as Ravaut claims, hypertonic salt solution robs the direct injection of the irritating effects of neosalvarsan, it might be well to use hypertonic salt solution as a basis for the dilution in the method of Swift and Ellis. One very advanced case of taboparesis, No. 28 of our series, was treated by the method of Swift and Ellis and by the direct method at various times. The patient finally died. Grossly, a little congestion of the meninges was found at necropsy, but sections studied by W. G. Spiller failed to show definite evidence of irritation. One case of paresis treated by both the direct and indirect methods, No. 34, shows marked improvement after failure to make any impress by seven intravenous injections given at weekly intervals and a number of injections of sodium cacodylate in 15 grain doses. The other two paretics are *in statu quo*. Two of the tabetics have shown marked improvement clinically, Nos. 26 and 27. They have received but two Swift and Ellis injections each. On the other hand, we have had two cases of tabes not included in our series, one with absent knee-jerks and lightning pains, the other with pupillary rigidity, absent knee-jerks, vomiting without pain, paresthesia and tabetic sphincter, both of whom recovered under intravenous treatment and mercury and iodids by mouth. The former, less marked, made an absolute recovery clinically and serologically, the latter has become subjectively symptom-free, knee-jerks now being present by reinforcement, vomiting, paresthesia and lightning pains totally relieved, the pupillary rigidity uninfluenced, serum now negative, but spinal fluid has not as yet been examined. These cases prove our previous statement that if recognized early, and this includes careful clinical and serologic study, tabes may prove amenable to intravenous injections together with mercury and iodids by mouth. In later cases, the value of the Swift and Ellis and direct methods are still *sub judice.*

ABSTRACT OF DISCUSSION

Dr. Edward L. Tuohy, Duluth, Minn.: Did Dr. Robertson find, in his experience, any marked evidences of difference in the various forms of this disease? It is said that in the Orient syphilis is more severe than in civilized countries. It is also said that it is more prone to attack the central nervous system. There happens to be a tremendous amount of discussion regarding the many heart-lesions that occur in lues and I would ask why this is. In tuberculosis we realize that when once an individual is tuberculous he is always tuberculous. It is shown that tuberculosis originates, as a rule, in childhood and such an individual will remain tuberculous thirty or forty years after inoculation. The same thing applies to lues; when once inoculated the individual remains syphilitic throughout his life. Regardless of all treatment the spirochete remains in the tissues until the end of the man's life. In the course of time, for some unknown cause, special predilection is manifested for some particular organ or tissue, after a period of apparent latency. In some instances this latency is so well concealed that only a Wassermann test will reveal it. The spirochetes lodge here and there in the body and the central nervous system is frequently involved. Often the "hit and miss" treatment may do good, but, on the other hand, may do harm by upsetting the immunizing processes that the body has developed.

Dr. B. F. Diseroad, Philadelphia: Will Dr. Robertson explain the following condition and state if in his experience he has made the same observation? We find a number of individuals with syphilis of long standing who give a history of chancre twenty or twenty-five years previously. This is followed by a long period of latency with the individual apparently enjoying good health, when suddenly manifestations of the disease crop out, either as tubercle syphilids, gumma of the internal organs and superficial structures, or of the central nervous system. Why then do these tertiary lesions following this latency occur singly in one of these various locations? All of these patients not treated for syphilis developed symptoms indicating lesions in cord or central nervous system. Some years ago I treated an elderly person who gave a history of recent trauma, but no history of any initial lesion. In the limb injured a gumma developed, but a clinical diagnosis was not made until symptoms of a lesion of the central nervous system cropped out, which was proved by a 4-plus Wassermann. Salvarsan caused an arrest of symptoms and the gumma promptly disappeared.

Dr. A. J. Caffrey, Milwaukee, Wis.: I think Dr. Robertson is wise in bringing out the point concerning the elimination of the primary chancre in syphilis. I know of a surgeon in Milwaukee who punctured his index finger while circumcising a primary chancre. No chancre appeared as a result but the secondary symptoms of syphilis appeared after a few weeks. He went on to an advanced paresis from which he died. Evidently this was a case in which the man became infected at the time of the circumcision without the appearance of a chancre. Dr. Lorenz of the state insane asylum at Madison, Wis., reported some success in the treatment of these cases, at a meeting of the Wisconsin State Medical Society. He gave neosalvarsan in minute doses—not by the Swift and Ellis method but by direct intradural injections.

Dr. J. V. Klauder, Philadelphia: In a study of the cerebrospinal fluid from syphilitic patients, in a series of cases greater in number than those given by Dr. Robertson, the following results were obtained. Our list of cases does not include any of primary syphilis. In 70 per cent. of patients with secondary syphilis, we obtained some evidence of an abnormality of the cerebrospinal fluid. Ravaut gives 67 per cent.; Dreyfus 80 per cent. In our series of tabetic cases we obtained a positive Wassermann in the serum in 62 per cent. of the cases. Swift and Ellis and Hauftmann both report 66 per cent. The Wassermann in the spinal fluid in the same series was positive in 82 per cent. of our cases, and Swift and Ellis report 87 per cent. The spinal fluid in all of our tabetic cases showed some evidence of an abnormality, except one, a clear-cut case, in which the spinal fluid was normal. In the same series, about one-half either denied infection or had mild secondaries. Attention has already been called to this, especially by Mott. Many of the tabetics gave a history of what was no doubt mixed infection; I believe this occurrence of mixed infection is more common than is usually accepted. The published reports of the intraspinal treatment of tabes and paresis are somewhat contradictory. The literature on this subject is rather confusing. Many do not countenance subdural injections of any character in the treatment of lues. In the Swift and Ellis treatment the dose of salvarsan or neosalvarsan contained in the serum is indefinite and variable. In the direct intraspinal treatment Ravaut advocates the injection of a rather large amount of salvarsan in a hypertonic salt solution, as much as 12 mg. Marked symptoms of irritation following this plan of treatment have been reported. We have injected 20 mg. of neosalvarsan intraspinally, which was followed by marked symptoms of irritation, in some cases. We do not believe that the efficiency of the treatment depends on the large dose injected. Ogilvie advocates the direct intraspinal injection of neosalvarsan in small amounts not exceeding 1 mg. No definite plan of direct intraspinal treatment has yet been formulated. The Swift and Ellis technic is a matter still *sub judice.* We believe that the most accurate plan so far as dosage is concerned, is first, to remove some of the patient's serum, following this by an intravenous injection of the dosage decided on, and, finally, to introduce into the inactivated serum a definite amount of neosalvarsan not exceeding 5 mg., which should be given subdurally. This method also possesses the advantage of saving considerable time, and permits the treatment of several cases in the time usually allotted for one Swift and Ellis treatment.

Dr. W. W. Tompkins, Charleston, W. Va.: What observations have been made in treating cases of syphilis of benign character as found in the negro? Of the negroes in my community many are intemperate, ignorant, suspicious, and will not carry out any directions given them in the way of treatment. If they come with a chancre one can do practically nothing after making the diagnosis. When the secondaries appear it is difficult to make them out because of the color. There is one point of interest, however, with regard to the occurrence of syphilis in the negro. I have observed that certain glands become enlarged, but the patients go on from year to year and do not suffer from the disease. So far as the late symptoms of the disease are concerned, such as locomotor ataxia and paresis, they are the rarest things in the world among the negroes. The glands that become infected are the cervical; they enlarge and after awhile they suppurate, then heal, leaving scar-tissue with more or less deformity. The surprising thing about these cases is that, with little or no treatment and in a class of patients that are often underfed and overstimulated, the symptoms should be so mild and free from serious complications or sequelae.

Dr. W. E. Robertson, Philadelphia: I have had little experience with lues in the colored race, so that I am unable to state whether or not grave lesions are common among negroes. In a few instances I have seen optic atrophy, tabes and other evidence of profound involvement of the nervous system in the negro, and such cases I believe are fairly frequent in the wards of the Philadelphia General Hospital. Concerning the modern treatment of luetic infections, we feel forced to utter a note of warning. The rapidity with which primary and secondary lesions disappear after an initial intravenous injection gives a false sense of security to the patient and increases the moral obligation of the physician. Unless he makes clear the necessity for careful laboratory studies, both for diagnostic purposes and as a guide to treatment, there will probably be many more tertiary and paraluetic (so-called) wrecks than confront him now, as a result of the mercury and iodid plan of treatment. Consistently treated, both intravenously and with mercury in some form, it is probable that every patient would make a complete recovery; neglected it is still problematic how large a proportion can be saved by subdural therapy. We feel certain that no one in whom sequential exudation and inflammation has occurred can hope for much from any form of treatment. We also believe that when subdural treatment is practiced the dose injected should not exceed 5 mg. and as the dosage under the Swift and Ellis plan must be speculative, it would seem better first to remove the patient's serum, separate and inactivate it, then prepare the intravenous injection, removing an amount not exceeding 5 mg., which should then be injected in the subdural space after diluting it in the previously inactivated serum. The rest of the salvarsan solution should then be given intravenously.

OSTEOPLASTIC SURGERY OF THE FACE*

W. WAYNE BABCOCK, M.D.
Surgeon to the Samaritan Hospital
PHILADELPHIA

ALTERATIONS OF THE FACIAL CONTOUR BY THE IMPLANTATION OF FAT

The modifications that the facial contour undergoes in the adult are dependent chiefly on alterations in the amount of subcutaneous fat. In the operative modification of the facial contour no substance is as well adapted for the purpose as adipose tissue. Bits of free homoplastic fat when properly imbedded subcutaneously find ready attachment, do not provoke serious inflammatory reaction and retain, after vascularization, their storage capacity for hydrocarbons. Transplanted fat may under conditions of increased nutrition undergo a certain amount of hyperplasia, and may waste during starvation. The transplanted fat when vascularized remains fixed in position and, unlike paraffin, when imbedded under the skin shows little change in outline, does not produce hyperemia of the overlying skin or marked fibroconnective tissue formation. In 1907 I[1] reported several operations in which free transplants of fat were used to isolate nerve trunks that had been subjected to operation. Recently Binnie[2] has reviewed the literature and has indicated many operative procedures in which free transplants of fat are of value.

My attention was first directed to the advantage of fat transplantation for the correction of facial deformity by a patient who had suffered extensive necrosis of both cheeks following the injection of paraffin by one of the most widely advertised "beauty doctors." The disfigurement was so great that the patient had been a recluse for six years. After excision of the scar tissue and the formation of cutaneous flaps, the depression remaining on the one side was so noticeable that finally a flap of fat was dissected subcutaneously from over the malar bone and turned down and imbedded, giving a satisfactory cosmetic effect. Later a patient presented himself with a marked facial asymmetry from lack of development of the lower jaw, particularly on the left side, following an ankylosis of twenty-four years' duration. After a bilateral arthroplasty a segment of one of his costal cartilages was implanted in the chin, and finally through an incision placed underneath the edge of the mandible, a subcutaneous pocket was formed and the sunken left side of the face contoured with bits of fat taken from the subcutaneous tissue of the patient's abdominal wall.

The implantation of the fat is useful after the removal of tumors or the liberation or resection of scars which leave secondary unsightly depressions. Fat may be also implanted for bony disfigurements, as after impacted fractures of the malar or frontal bones. After disfiguring operations, as on the frontal sinuses, and for certain congenital or acquired deformities such as receding chin, asymmetry of the maxillary bones and the like, the implantation of fat is useful. For the subcutaneous imbedding of fat the cutaneous incision need not be large, and should, if possible, be placed at some inconspicuous point as along a normal wrinkle line or beneath the jaw. The subcutaneous tissues are separated by a knife or by tunneling with blunt-pointed scissors. After arresting hemorrhage, bits of fat of sufficient size to correct the deformity are introduced and held in the pocket, which obviously must be of proper size and situation, by subcutaneous sutures of fine catgut. We have usually found it undesirable to suture the fat in position, as this prevents the adjustment of the imbedded fat to the containing cavity. The fat may be introduced in the form of small portions or strips and the subcutaneous closure should be sufficiently tight to prevent any extrusion of the fat from the limiting pocket. The skin is finally approximated by an intracuticular or very fine epidermic suture. Fat may be obtained from the adjacent subcutaneous tissue or from the abdominal wall. We have, thus far, not employed fat from another person. Although we have used larger quantities of fat in the restoration of the contour of the breast after the removal of benign tumors than are usually required in facial surgery, we have had no suppuration or evidence of absorption of the imbedded tissues.

THE CORRECTION OF SADDLE-NOSE

In certain cases in which the bridge of the nose has been lost without destruction of the tip or alae, a satisfactory bridge can be formed of metal, cartilage or bone. We have employed portions of a rib, costal cartilage, and tibia, the last method presenting certain advantages. An incision about 1 inch long is made from the base of the nose upward in one of the wrinkle lines of the forehead and is carried to the bone. With blunt-pointed scissors or a separator carried close to the nasal bones, the soft tissues over the bridge of the nose are thoroughly separated and elevated. A tibial transplant is removed, cut to appropriate shape, and after arrest of oozing is slid into position from the frontal incision, its ends respectively abutting against the frontal bone, and the cartilage just a short distance above the tip of the nose. If necessary two or more short strips of bone may be superimposed. The deep tissues are closed with fine catgut and the skin by a subcuticular or delicate epidermal sutures. The operation has the advantage of simplicity, slight disfigurement, of a location of the incision in an area susceptible to sterilization. Local anesthesia suffices. In one instance, after paraffin had failed to maintain its position, we split the tip of the nose just above the nares and imbedded a section of costal cartilage with excellent immediate effect, but infection and extrusion of the fragment followed.

THE CORRECTION OF SKULL DEFECTS

Silver plates placed under the scalp to cover defects in the skull present a large area of metallic surface that stimulates serous secretion. In a very limited experience we have found it necessary repeatedly to evacuate such secretion until finally infection has occurred and it has been necessary to remove the plate. In two instances we have remedied the defect in the skull by bridging with Lane plates which were so bent as to conform to the contour of the skull and were firmly fastened to the bone by screws. In the first instance the large flap of bone which had been separated fell to the floor during the operation and, of course, was not replaced. The patient was relieved of Jacksonian epilepsy but a large depressed area remained in the parietal region, which, as he bent forward, filled and caused so much vertigo that the man could not work. The disfigurement and symptoms were relieved by the use of the Lane plates, the thickened dura being lifted and fastened to the steel bars by interrupted sutures. In a second patient, a luetic woman, a disfiguring defect in the frontoparietal region was first partially corrected by a silver filigree. The silver filigree caused no irritaiton but was so soft as to become depressed and we later removed it and substituted Lane plates with the satisfactory cosmetic result.

IMPROVISED METHOD OF CORRECTING DEFECTS OF THE MANDIBLE

Modified Lane plates fastened to the bones by screws may be used in an emergency to take the place of absent portions of mandible. In one of our patients a large part of the left side of the face including the ramus and part of the body of the lower jaw was blown away by the charge from a shotgun. After operations to overcome the ankylosis and to restore the lining and covering of the cheeks, one arm of a three-pronged Lane plate was broken off and the plate fastened to the body of the jaw so as to form a new angle and a new ramus. Despite the attenuated and densely cicatricial tissue in which this flap was imbedded, it was worn with great improvement for over six months, being finally removed because the sharp rough angle of the plate penetrated the skin and produced a slight sinus without, however, much irritation.

RHINOPLASTY

In the Italian method of rhinoplasty in its original or one of its modified forms, it is usually desirable to swing a pedunculated supraorbital flap down on the nose leaving a defect in the lower part of the forehead that must close by granulation or skin grafting. We have found it of advantage in such a case, after removing the flap, to make a second incision close to the hair line, and, after mobilizing the tissues of the upper frontal region, push them down and accurately fill in the gap above the eyebrow. In this way little disfigurement remains in the lower part of the forehead and the granulating cicatrix is left close to the hair line where it may be covered by a hat or by a suitable dressing of the hair.

ENLARGEMENT OF THE EXTERNAL NARES

Much attention has been given to obstruction in the upper air-passages, and the influence of such obstruction, whether in the nose or pharynx, on the shape of the mouth and the development of the bones of the lower part of the face, requires no further emphasis. Apparently, however, little attention has been paid to obstruction due to the small size of the external nares. Fortunately, by resection of the skin and thin cartilaginous walls above the nasal openings, small and round nasal openings may be converted into fair-sized keyhole apertures. With a very sharp knife, wedge-shaped incisions are made. Great accuracy in planning the incisions is necessary to produce satisfactory symmetry of the two openings, and if the surgeon has not considerable dexterity it may be better to enlarge each opening by a punch to ensure uniformity.

The wound edges, after the wedge-shaped excision, are accurately united by fine horsehair sutures and permitted to heal without an external dressing under a scab. The stitches should be removed on the second or third day, by which time primary union will usually have occurred. By this method it is possible to increase the nasal aperture a third or more and to give the patient a corresponding relief from his external nasal obstruction.

2033 Walnut Street.

ABSTRACT OF DISCUSSION

Dr. M. I. Schamberg, New York: I am particularly interested in Dr. Babcock's method of transplanting fat from one portion of the body to another, and it sounds like a decided step in advance. The only question raised in my mind was whether or not that fat would in time be resorbed. I would be glad if Dr. Babcock would outline the behavior of this fat and the length of time that it will remain after the operation. I wonder whether he has had such an experience in using steel screws as I have had, in that they become badly rusted owing to the amount of oxygen in the tissues and the amount of moisture we find there. I do not believe much in Lane plates. I have not had recourse to the Lane plates but have had a case in which I was operating for marked prognathism, in which I took out a section of the jaw on both sides and brought the jaw back and held it in place by steel plates, which I removed subsequently. They were badly rusted and I believe were a source of irritation. I imagine the Lane plates retained only for a short time would do no harm. The results in this particular case of marked prognathism, however, have been as ideal as any I have seen. In another case a man who had been operated on in another department of the Post Graduate School of Medicine had lost his entire nose, save a little tip which flapped up and down and in which the opening afforded a full view of the nasal chamber and the accessory sinuses. In this case we are desirous of doing a cosmetic operation. Dr. Mitchell has devised a plan to restore the bridge between the nose and the mouth, and we are going to make a frame-work to be attached to a plate in his mouth and to run up into the nasal chamber. It will be cleansed through the mouth. The top of this appliance will be held in position, and the plastic work done over this frame-work. The skin can be folded over from the forehead, and I think we can give the patient a fairly good contour over the nasal chamber. The cleansing can be done by irrigation through the nostrils, or by the removal of this plate in his mouth, which will be supported by several teeth. We shall endeavor not to have any pressure on the bony structure above so that there will not be any resorption in this region. In another case a good portion of the jaw was removed from immediately above the angle to the bicuspid angle, and the remaining parts were held in place by silver plates riveted directly to the bone. This case resulted beautifully from a mechanical point of view. The patient immediately after the operation was able to open and close the jaw, and to masticate with absolute articulation, but six months later the bone to which the silver plates were anchored necrosed and we had to remove the plates. I am not much in favor of permanent metallic attachments to bone as it interferes with the filling in of the tissue.

Dr. H. S. Dunning, New York: Will Dr. Babcock state how the Lane plates are held in when a greater part of the bone is carried away—whether they are attached to the end of the bone or to the soft tissues?

Dr. Wayne W. Babcock, Philadelphia: Many of these things have been alluded to in a fragmentary way and of course require working out. As to the permanence of the irritation in tissues produced by the Lane plate, I think it is largely a matter of infection. With a clean Lane plate imbedded or fastened to the bone, and without infection, I have seen no marked corrosion. Some of these I have seen in place for a number of years in connection with long bones. In one case the plates remained for three years and caused no irritation. Some of these plates were fastened with silver screws, and some with a steel alloy screw which is supposed to be non-tarnishing, though it does tarnish. I think if we have an opening and access to outside air, trouble usually ensues from this oxidation. That is the particular trouble in operating about the jaw; it is so hard to put these plates in the jaw without some communication from the outside, and that means, usually, that sooner or later the plate has to be removed. In one case we screwed the fixed Lane plate to a portion of the bone proper. It was fastened by two screws in front and fixed firmly and at rest in the tissues. In that case if the plate had been smoother I believe it would have been retained, because when the plate was finally removed there was no marked corrosion. As to the resorption of fat, for about twelve years we have been transplanting skin with the subcutaneous tissue to other parts of the body and we notice that as the tissue improves in nutrition, the fat with the subcutaneous layer becomes larger, so much so that at times it gets in the way. Apparently as the general tissue improves, tissue taken from the abdomen and put on the hand or arm will increase also. In a number of cases we have found it necessary to cut away fat which had so increased in size, and in the tissue removed the vascularity was perfect. I have under my care now a case of transplantation of fat which shows every evidence of softness of the tissue and the maintenance of the contour and vascularity. It seems that the storage capacity of the fat for carbohydrates has been transferred with the growth and is still being maintained.

Experimental Research and Medical Progress.—It may be taken as an axiom of medical science that everything of value in medicine and surgery has arisen from the applications of experimental research. Nor can future advance be made by any other method than the research method. It is true that accident may teach occasionally, as it did, for example, in the dreadful burns unwittingly inflicted on themselves and patients by the early experimenters in Roentgen-ray therapy and diagnosis. But accident is only the most blundering type of experimentation, and results obtained by its chance agency do not really invalidate the universal law that man only learns by experience, or, in other words, by research. Research is, after all, only the acquisition of fresh experience by the trained expert, usually led on to his experiment by inductance from other known facts.—Benjamin Moore, *Medical Journal of Australia.*

RENAL INFECTION

A FURTHER EXPERIMENTAL STUDY OF ITS RELATION TO IMPAIRED URETERIC FUNCTION *

WILLIAM HOWARD BARBER, M.D.
AND
JOHN WILLIAM DRAPER, M.D.
NEW YORK

Injuries, inflammation, neoplasms, and congenital defects of the ureter, urinary bladder, or associated organs could be more often successfully treated had we an effectual method of entero-ureteral transplantation. It is pointed out by Watson and Cunningham[1] after condemning all operations for diverting urine, with the single exception of Maydl's, that "the very large proportion of cases have proven fatal either as a result of the operation or because of the renal lesions which are produced later by ascending infection from the intestinal tract."

Eisendrath[2] holds that "reimplantation of the ureter into the lower bowel is impracticable on account of the irritant action of the urine on the mucous membrane, causing persistent diarrhea, and on account of the frequent occurrence of ascending infection." Carl Beck[3] adds "infection of the kidneys secondary to the operation and the difficult control of urination" as "principal drawbacks." In addition to ascending infection, colitis, difficult control of urination, shock, peritonitis following technical errors, may be mentioned to explain the general failure of entero-ureteroplasty. Maydl's block transplantation seems to have met with most success, since, as Cunningham[1] puts it, "ascending infection is less probable . . . because of the protection afforded by the preservation of the natural relations." It has been our object in this paper to study these "natural relations," define them, and estimate their respective values. It was hoped to gain information on which to found a more satisfactory technic for an entero-ureteral operation. Evidently it must be based on inductive knowledge of the obscure physiology of the ureter. Given the normal gross anatomic relations of kidney, ureter, and bladder intact, it is taught that renal infection may be urogenous.[4] Cases of probable ascending infection are reported clinically.[5] Individual opinion as to the occurrence or non-occurrence of "ascending infection" seems to be as diverse as the proven clinical cases are rare.

ESSENTIAL STATE OF BLADDER FOR ASCENDING INFECTION

Guyon and Albarran[6] pointed out that bacteriuria and retention were necessary for kidney infection. Guyon[7] emphasized bladder sensibility and abnormal contractility with coincident cystitis. Courtade and Guyon[8] emphasized retention. Brewer[9] reviewed the work of these and other investigators and concluded the essentials to be (1) chronic cystitis; (2) acute retention with spasmodic contraction of the detrusor; (3) mechanical interference with ureteral sphincter. In our experiments we have not attempted to increase whatever retention may physiologically exist in dogs, although we realize that it may be important in the production of renal infection.

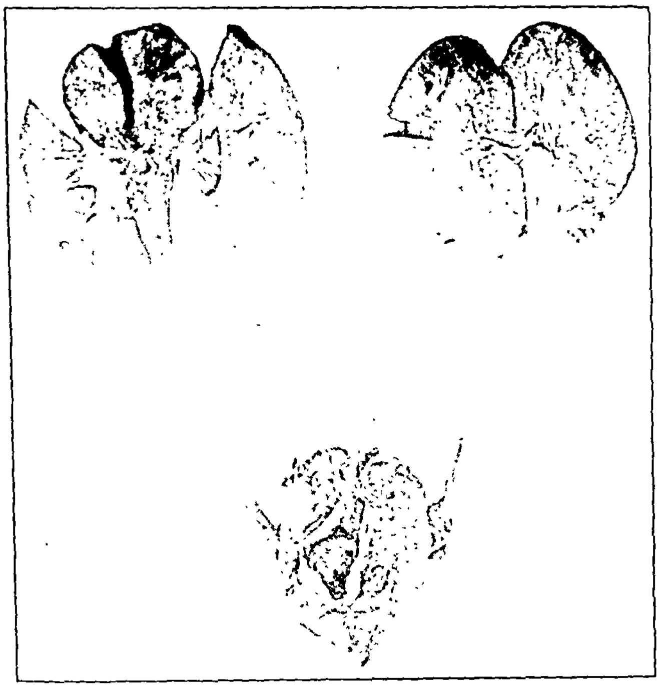

Fig. 5 (Dog 83).—Pyelonephritis following stripping ureter and cutting valve; cut surface (left) showing foci at cephalad pole.

MECHANISM OF ASCENSION

It was held by Guyon[7] in 1890 that cystitis may give rise to ascending nephritis. It is interesting to compare the findings of G. G. Smith's[10] analysis of ninety-eight cases of cystitis from the wards and the outpatient department of the Massachusetts General Hospital in which he pointed out that certainly not more than five had given rise to pyelitis by the ascending route, and that even this small number was doubtful. Renal infection from cystitis has been proved possible by different experimenters since, but the mechanism of its production is far from agreed on.

Obviously, given a suppurating bladder, infection may ascend to the kidney outside the ureter through the ureter wall or through the lumen of the ureter. If it travels outside, it may follow the course demonstrated by Samson[11] and designated vesico-utero-ovario-renal anastomosis, and follow these blood vessels; or by the lymphatics, as demonstrated by Stewart[12] in eight out of ten transplanted dogs' ureters. The infection may ascend within the ureter wall apparently only under a pathologic condition of the ureter itself, such as shown by Samson's[11] clinical case of purulent cystitis, ureteritis with exudative swelling and occlusion of the ureter and suppurative nephritis. If the infection ascends by the lumen of the ureter, several courses have been held by different investigators. It does not seem necessary to mention the method suggested by Kelly and repeated by Samson[11] of aspiration with air through the ureter during cystoscopy with the patient in the knee-chest position. Motility of the micro-organism is the means suggested by Guyon and Albarran,[6] on the basis of the difference in time of ascent between an inert colored particle and the colon bacillus; the ratio being roughly 2:1. If the organism is a coccus and therefore immotile, it is thought to ascend partly by the processes of reproduction and extension along the ureteral wall, and partly by a to-and-fro motion of the ureter itself. Orth and Jacobelli supported Guyon and Albarran. Le Brigand[5] in 1900 concluded similarly from his clinical observations. This to-and-fro movement is qualified still further as "countercurrent" and "eddy" by Adjevoli.[11] C. J. Bond[13] experimenting with insoluble dyes described a mucous current in a partially collapsed ureter. Anastalsis and reflux complete the means of possible intra-ureteral ascension. Reflux has been described as occurring in rabbits by Lewin and Goldsmith, Courtade and Guyon,[8] Jacobelli, and Marcus.[11] Jacobelli maintains that the fluid must be injected suddenly[14] into the bladder for it to ascend the rabbit's ureter. Courtade and Guyon observed reflux in dogs. Marcus further showed reflux of urine in rabbits possible by anastalsis or vesical contraction when the ureters were distended. Disse[11] explained the patency of the ureteral valves under such circumstances by contraction of the longitudinal musculature of the ureter, thus converting it into an inflexible

tube. On the other hand, Young[15] in several cases failed to get reflux in dog's ureter after injecting the bladder with colored solution. This agrees with the findings of Draper and Braasch.[16] Samson[11] tried out anastalsis and reflux in nineteen dogs. To each bladder was attached a normal ureter, a ureteral stump, and the reimplanted cut distal end. In no case having normal valve or with valve absent did he observe reversed ureteral current. But he held reflux possible in conjunction with diseased ureter. May it not be that the amount of injury to the ureter explains the varying results of these different investigators? We have distended the dog's bladder by a 4½-foot water column and noted no reflux in normal ureter with normal valve or in stripped ureter with normal valve. Suddenly injected fluid as observed by Jacobelli was noticed by us to collect slowly and drop from the cut end of stripped ureter with cut valve.

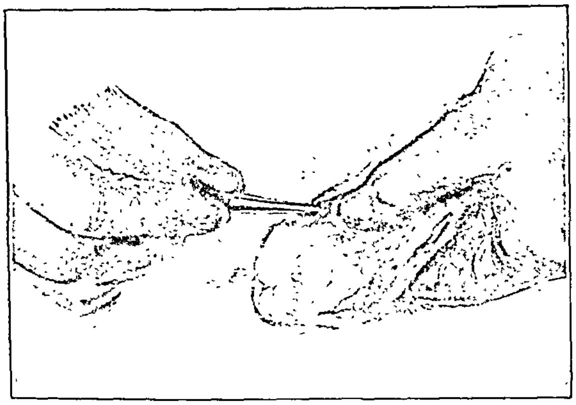

Fig. 10.—Technic of isolating and stripping ureter and irritating suppositional ureteral nerve plexus.

EMBRYOLOGY

It is known[17] that at the fourth week, the ureteric part of the kidney is apparent as a dilatation at the caudad end of the wolffian duct, near the cloaca; the nephritic tissue being represented in the sacral region. At the beginning of the second month the ureteric bud grows out against the nephritic tissue in the sacral region. By the end of the second month the renal bud has ascended to the lower part of the lumbar region, passing dorsad to the wolffian body; the ureter and its pelvic calyces can now be recognized. When we consider mammalian embryology and the close relationship of birds with their permanent cloacal arrangement to the mammals, there appears a phylogenetic as well as an ontogenetic basis for believing that the human body should be capable of assuming vicariously the recently lost function of storing urine. Furthermore, Huntington[18] calls attention to the origin of the bladder from the cloacal or intestinal space and to the relationship as shown in one of our larger American lizards, *Igriana tuberculata,* between the adult reptile and certain stages in the development of the mammals respecting the common termination of the genito-urinary and intestinal tracts.

ANATOMY

Anatomically the ureter is of course well understood. The vesical end is reinforced by a fibrous sheath which envelops the ureterovesical junction. The ureteral musculature is replaced as it reaches the vesical submucosa by longitudinal fibers arising from the bladder and paralleling the ureter within the bladder wall. The ureteral mucosa blends with that of the bladder, forming the orifice of the ureterovesical valve. The ureter is enclosed throughout in peritoneum, beneath which it derives blood, lymph and nerve supply. The blood supply has been mentioned. The lymphatics have been carefully worked out by Sakota. The nerves of the ureter are derived from the sympathetic.

PHYSIOLOGY

Physiologically much less is known. In speaking of the nerve control of the ureter Lucas[19] says:

> I believe that further research will justify the general division of the ureter into the following two portions: 1. The funnel-shaped portion cephalad to the isthmus contained in the renal pelvis and probably partaking of the nerve distribution of the kidney. 2. The straight portion extending from the isthmus to the bladder, which may be subdivided into (a) a cephalad third, containing nerve endings in its wall; (b) a middle third deficient in nerve endings, and (c) a caudad third, adjacent to the bladder and partaking to some extent in the nerve distribution of the bladder.

Von Bardeleben[20] holds that the renal plexus supplies the pelvis and the cephalad half of the abdominal part: the spermatic, the caudad half of the abdominal part; and the hypogastric, the pelvic portion. Ganglia and nerve ends he found in adventitia, large at the ends and small in the middle of the ureter. Piersol[21] and Cunningham support Bardeleben.

It is evident that the origin of muscular contractions of the ureter, whether neurogenic or myogenic is not understood, but that it is a matter of observation that rhythmical contractions do exist. They occur in peristaltic waves, which, beginning with the kidney pelvis, progress toward the bladder at average intervals of 9 seconds in the dog, according to our own observations. Urine appears to be forced into the bladder by each peristaltic contraction. These contractions appear to be quite persistent as long as the normal relations of the ureter are preserved, but vari-

able in force and frequency when these are disturbed. Moreover, this irregularity in ureteral peristalsis seems to vary in direct proportion to the degree of trauma to the organ. We believe that a complete removal of the ureter from its retroperitoneal bed affords a valuable technical index for the experimental study of renal lesions. It has evidently entered as an unobserved and uninterpreted complex into much of the clinical and experimental study reported to date without having been given due consideration as a causative factor. In brief, ureteral dislodgment causes a condition roughly analogous to so-called "adynamic ileus" of the gut.

EXPERIMENTAL PROCEDURE

We present for consideration the following proposition: Given a foreign body cystitis the local factors determining infection are:

1. The ureterovesical valves, and
2. The peristalsis of the ureter.

These factors may be made experimental variants as follows:

By 1. Cutting of the valve.
2. Disturbance of ureteral peristalsis.
3. *Combination of* 1 *and* 2.
4. Ureteral circumcision.
5. Combination of 2 and 4.
6. Combination of 1 and 4.
7. Combination of 1, 2 and 4.

These may be considered in detail as regards experimental findings.

Our experiments have been made on dogs, forty in all having been used exclusive of Draper-Braasch series. Each dog had received a maximum dose of morphin sulphate per kilo of body-weight, followed by profound ether anesthesia. Each case was subsequently nephrotomized, and an appropriate section preserved for a microscopical index of normal kidney.

* The streptococcus and colon bacillus were found in both kidneys of No. 139. Streptococcus was found in left kidney of No. 151. No bacteriologic examination of right kidney of No. 151 was made. The presence of these organisms appeared to be due to post-mortem invasion.

1. *Cutting of the Ureterovesical Valve.*—See Draper-Braasch series. A further technical point in valve cutting that seems worthy of note is that in attempting to cut the valve either do not traumatize the valve area at all, which ensures the natural color relations, or traumatize severely, which converts the valvular orifice into an ischemic ring.

Result (10 cases): No substantial kidney change.

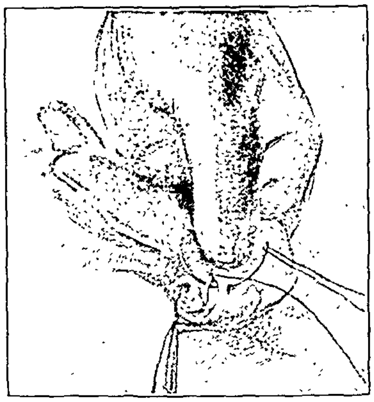

Fig. 14.—Technic of further step in circumcising ureter.

2. *Disturbance of Ureteral Peristalsis.*—In nine cases the ureter was removed from its retroperitoneal bed, stripped of every recognizable vessel, nerve and fascial connection from kidney pelvis to bladder insertion. In order to make sure that it was absolutely freed from all nervovascular connections throughout its course, as well as to disturb the nerve plexus in the adventitia of the ureter, the ureter was rubbed snugly with dry gauze throughout. It was then allowed to drop back into the peritoneal cavity.

In each case of these series a cubical foreign body infected with autogenous colon bacilli and other organisms, and of such shape as not to cause valvular ureteral obstruction, as suggested by Draper and Braasch, was placed in the bladder through a mesoventrad incision so that, as subsequent examinations of urine and bladder revealed, a purulent cystitis was produced.

Result (9 cases):[22] Hydronephrosis in various stages.

3. *Combination of 1 and 2.*—Result (10 cases): Pyelonephritis may follow. But the lower segment of straight portion of the ureter is supplied by the sympathetic through the vesical plexus. To eliminate a possible nerve control through such recurrent fibers the following observations were made by

4. *Ureteral Circumcision.*—In circumcising the valve an incision was carried about the ureterovesical implantation through the serosa, muscularis and submucosa to the firm, comparatively resisting, vesical mucosa. When completed this incision was carefully closed by continuous suture.

Result (7 cases): No kidney change.

5. *Combination of 2 and 4.*—Result (3 cases): Hydronephrosis.

6. *Combination of 1 and 2.*—Result (3 cases): No kidney change.

7. *Combination of 1, 2 and 4.*—Result (4 cases): No kidney change.

Therefore the severing of whatever nerve supply enters the ureter from the bladder appears to play no essential part in the possible renal infection.

CONCLUSIONS

Given an infected bladder and making due allowance for systemic and local resistance:

1. The ureterovesical valves can be cut without resulting renal infection. Duration of life indefinite.

2. If the ureter is circumcised to but not through the vesical mucosa the kidney remains normal. Duration of life indefinite.

3. Ureteral traumatism resulting in greater or lesser degrees of impairment of function as indicated by prostaltic paralysis, resulted in 75 per cent. of cases in hydronephrosis which in the early stages were not infected: a mechanically changed kidney which might or might not be infected later. Average duration of life, 30.33 days.

4. If the valves were cut and the ureters were paralyzed, hydronephrosis did not occur, but the kidneys underwent a primary infective change in 50 per cent. of cases. Average duration of life, 13.57 days.

At the beginning of this paper it was stated that our object was to study, define and estimate the respective values of the "natural relations" of the ureter.

The integrity of the "factor of safety" which protects the kidneys both from urogenous infection and from hydropic degeneration appears to depend directly on the unimpaired prostalsis of the ureter; indirectly on the integrity of the ureterovesical valve and most interestingly on the relationship btween these physiologic and anatomic barriers.

The authors acknowledge the constructive criticism of Prof. George D. Stuart and Prof. Douglas Symmers; also the detailed assistance of Dr. A. G. Bennett and Dr. W. C. Noble of the department of bacteriology.

104 East Fortieth Street.

ABSTRACT OF DISCUSSION

Dr. J. W. Draper, New York: I am glad to corroborate and endorse everything that Dr. Barber has said. The work is not yet finished. All these experimental studies seem never to come to an end. Nevertheless, I believe we are justified in saying that one may cut the valve without getting an infected kidney. Of course, all of these dogs operated on have been treated just as Dr. Braasch and I treated the first series, namely, in the bladder has been placed a cubical piece of coal which has been rubbed in the dog's own feces, thus securing an autogenous infection and a condition which is allied to, but probably not identical with human cystitis. Nevertheless, they pass a great deal of pus in the urine. Such a series will go on without any renal infection or general infection. If, however, in addition to cutting the valve, the ureter is deinnervated and devascularized by Dr. Barber's method, one is practically certain to get, or we have, in this last series, obtained quite constant results, namely, infection of the kidney. We are not prepared to say just how it occurs, but we are prepared to say that the kidney becomes infected. If, on the other hand, as Dr. Barber has said, the ureter is simply lifted from its bed, with an accompanying devascularization and deinnervation, except possibly for recurrent innervation that may come from the bladder—because we have not been able to cut through the entire mucosa without killing the dogs, and the circumcision which Dr. Barber has devised most ingeniously cuts off everything except that small vestigial remnant—one obtains an uninfected hydronephrosis, and one which differs somewhat from the transitory hydronephrosis which occurs after ligation or other mechanical obstruction of the ureter. Of course, we are not in a position to say positively that there is no mechanical obstruction to the ureter as a result of this extensive handling. It is quite conceivable that there may be considerable swelling, enough swelling of the lining cells to make a transitory semimechanical obstruction; but we believe that it is due to the complete paralysis which we have shown to exist as a result of the procedure.

---

[22] Barber, Stuart and Symmers: Hydronephrosis: An Experimental Study.

Dr. W. F. Braasch, Rochester, Minn.: The experiments carried on by Dr. Barber explain, at least partially, certain factors in the physiology of the ureter with which we have not been acquainted heretofore. It is evident from his experiments that the action of the ureteral peristalsis is important in preventing ascending infection. These experiments should be of practical value in connection with operations on the ureter. The Maydl and Coffey operations which have proved to be the most successful, in which the ureter is implanted in the bladder-wall, are both made with the idea of preserving the so-called ureterovesical valve. The importance of this valve in the first series of experiments on the ureter made by Draper and Braasch was not appreciated. We inferred that the preservation of this valve was of no importance, but Dr. Barber has shown that it is important if the blood and nerve-supply of the ureter above is not preserved. So the important point is that, while with the Maydl and Coffey operation the blood and nerve-supply may be destroyed, the ureterovesical valve is preserved and infection does not occur. That dilatation and insufficiency of the ureterovesical orifice is not of much importance in preventing ascending infection, provided that the ureter above is normal, is proved by a number of cases of cystitis in which, on cystoscopic examination, the ureteral orifice was greatly dilated. The bladder-fluid could be seen entering the ureter and returning again with each respiration and the pyelogram showed the bladder ureter to be greatly dilated. The ureter above the bladder was quite normal and with the catheter high up in the ureter the urine came from the catheter with perfect peristalsis, showing that the lower ureter is not of much importance provided the ureter above is normal. Dr. Barber's experiments should clear the way for more successful reimplantation of the ureter, which is not infrequently necessary.

Dr. John H. Cunningham, Jr., Boston: It has been fairly well established by many clinical observations and experimental studies that renal infection as an ascending infection by continuity from an infected bladder is rare, and when it does occur, is dependent on a disturbance of the normal function of the ureteral openings, associated with urinary retention and cystitis. With the preservation of the normal relations of the ureteral openings a protection to an extension of infection from the mucosa of the bladder up the ureter or the possibility of a reflux of infected urine must be discarded. Several years ago Dr. Garceau and I made a series of experiments bearing on this point. We injected a methylene-blue solution into the bladder of anesthetized dogs, varying the degree of pressure from a few pounds to that sufficient to rupture the bladder, and in no instance did the dye find its way up the ureter or even beyond the ureteral openings. This work has been repeated by Young, Draper and Braasch with the same results. On the other hand, with any disturbance of the normal condition of the ureteral openings, either congenital or acquired by changes in the musculature from long-standing retention of urine, ulcerations or new growths involving them, or ureteral calculi impacted near the terminal end of the ureter so that the ureteral mouth becomes patulous, renal disease may take place by an ascending infection. As has been stated, the essentials for ascending renal infections are a combination of factors, namely, an infected bladder, with an interference with the function of the ureteral sphincter. Whether or not the infection of the kidney may take place from an infected bladder by way of communicating lymphatics is chiefly speculative, although there is some experimental evidence that such is the case. This naturally brings us to ascending renal infection in those instances in which, by operative procedures, the normal relations of the ureteral openings are disturbed. All operative procedures except Maydl's, which removes the trigon with [illegible] openings undisturbed, destroy the muscular mechanism which prevents ascension from the bladder to the kidneys by way of the ureters, and the clinical observations show that the large proportion of such cases prove fatal as the result of the operation or because of the renal infection which occurs later by ascending infection. This includes the cases of ureteral implantation on the surface of the skin, in the vagina in the female, and in the intestinal canal. In fact, many instances in which Maydl's operation of implanting the trigon into the intestinal canal with the ureteral orifices undisturbed have resulted in ascending renal lesions. The theory of this operation is correct, yet it is difficult of performance, and it is not beyond a most likely probability that the ureteral mechanism is disturbed in its performance. It is for this reason that Dr. Watson and I have maintained that double nephrostomy is preferable to bilateral ureteral implantation by whatever method. I cannot agree with Dr. Barber that the implantation of the ureters into the intestinal canal has any sound foundation, because of the embryologic feature of their once having been a part of the common excretory apparatus, the cloaca. Nor do I believe that the phylogenetic relationship of birds and mammals is any sound argument that the human may, on an ontogenetic basis, assume that which is a phylogenetic fact, because ontogeny is simply a reflection of phylogeny, and ontogenetically there is a further specialization of tissue which renders the comparison of conditions from an ontogenetic and phylogenetic point of view entirely separate. With regard to the experimental features, Dr. Barber has once again proved that a disturbance of the sphincteric mechanism at the ureteral outlet into the bladder may result in renal lesions, and has emphasized that ureteral traumatism results in an impairment of ureteric function and produces kidney changes which frequently lead to subsequent infection of the impaired organs. He has shown that disturbance of the natural relations of the ureters proper and their valves lessens the value of the kidney and leads to subsequent infections. This important piece of experimental investigation corroborating the already established clinical facts strengthens my belief that, when it is necessary to dislodge the ureters permanently, bilateral nephrostomy is to be preferred to ureteral implantation by whatever method, because, by this method of diverting the urinary stream, renal infection of a serious character is less likely to take place. It is by just such pieces of experimental work along the lines of comparative pathology that we shall find the explanations of clinical observations and through them receive information helpful to our understanding of clinical facts.

Dr. D. N. Eisendrath, Chicago: I made quite a study of the lymphatics of the ureter in connection with some recent experimental work. We know that there is a set of lymphatics in the mucous membrane passing in and forming a network around the epithelial cells of the ureter, and communicating with the lymphatics of the submucous layer, which again communicate with the lymphatics in the muscular and fibrous coverings. The interesting problem to me is that, in spite of the fact that Dr. Barber cut through all of the coats except the mucous membrane by his incision above the bladder, leaving only the mucous coat, he should have had such an ascending infection as he has shown. The old theory was that all of the infections traveled from the bladder to the kidney by reason of continuity in the mucous membrane. It looks as if his work were a substantiation of the old theory, whereas the new view is that infections go by means of the deeper lymphatics.

Dr. W. H. Barber, New York: There was no increased fixation for colon bacillus from the time the dogs were first operated on until a week had elapsed after operation and the organisms found on culture from the bladder, ureter or kidneys were the colon bacillus, the streptococcus, or both.

Answering Calumny.—If a man has reported to you, that a certain person speaks ill of you, do not make any defense to what has been told you; but reply, the man did not know the rest of my faults, for he would not have mentioned these only.—*The Encheiridion.*

NECROTIC BONE AND THE SUBSEQUENT CHANGES WHICH IT UNDERGOES [*]

D. B. PHEMISTER, M.D.
CHICAGO

Bone destruction may be molecular, to which the name of caries is applied, or *en masse,* when it is spoken of as necrosis. Caries is usually produced by the milder and slowly acting circumscribed affections in which bone destruction keeps pace with bone death. On the other hand, necrosis results from the more rapidly acting and severer processes in which a more or less extensive area becomes involved and destroyed in a comparatively short time and which persists for an indefinite period before removal. Before considering the special subject of necrotic bone and its subsequent changes it is well to glance briefly at the subject of tissue necrosis in general in order to determine the differences which obtain for bone, and the reasons for their occurrence.

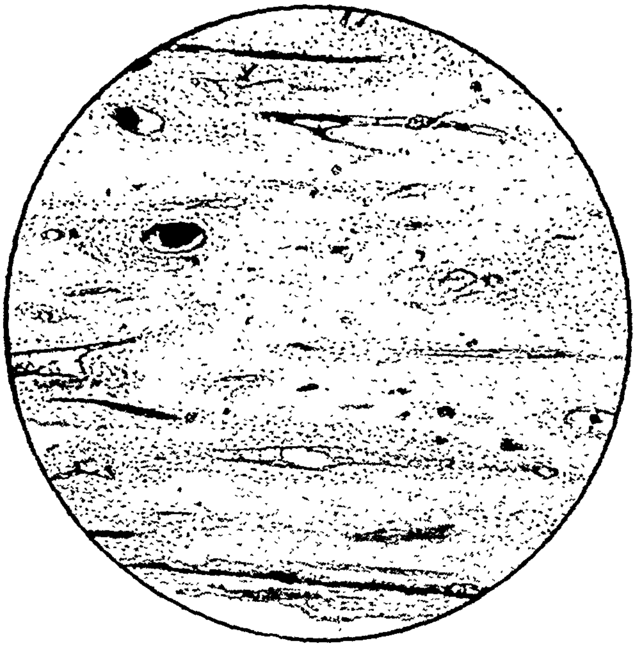

Fig. 1.—Transplant 164 days old showing the dead cortex about one-half substituted by new bone.

The death of tissue *en masse* occurs either from infection or from circulatory disturbances which may be acute or chronic in nature. When due to an acute infection the necrotic tissue is usually rapidly broken down by the action of cytolytic agents and to a less extent of phagocytes, and with the other products of inflammation makes a purulent or ichorous accumulation. Such accumulations are either discharged from the body or are slowly absorbed. Necrosis in chronic inflammatory processes, as tuberculosis and syphilis, consists more in a death of the hyperplastic granulomatous tissues which have formed than of preexisting cells affected by the process. It results in the formation of caseous material, the fate of which may be any one of the following: liquefaction and discharge, absorption, encapsulation or calcification.

Necrotic tissue resulting from circulatory disturbances behaves differently according to the presence or absence of infection. If in such tissue an infection occurs, the destructive changes are accelerated, and combined with the inflammatory reaction, abscess or moist gangrene results. If no infection is present, as in the case of bland infarcts of the kidney and spleen, the necrotic tissue persists as a soft cheesy mass which is slowly replaced by an ingrowth of the surrounding connective tissue.

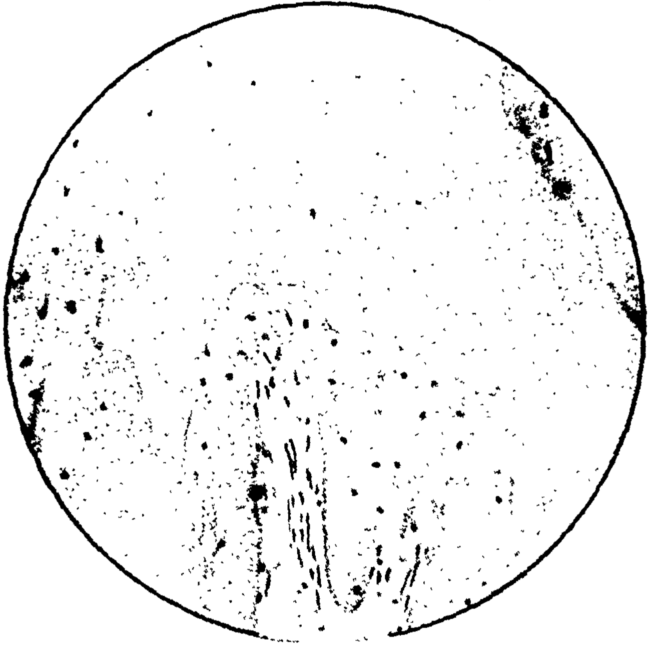

Fig. 2.—Same transplant as shown in Figure 1 under high power.

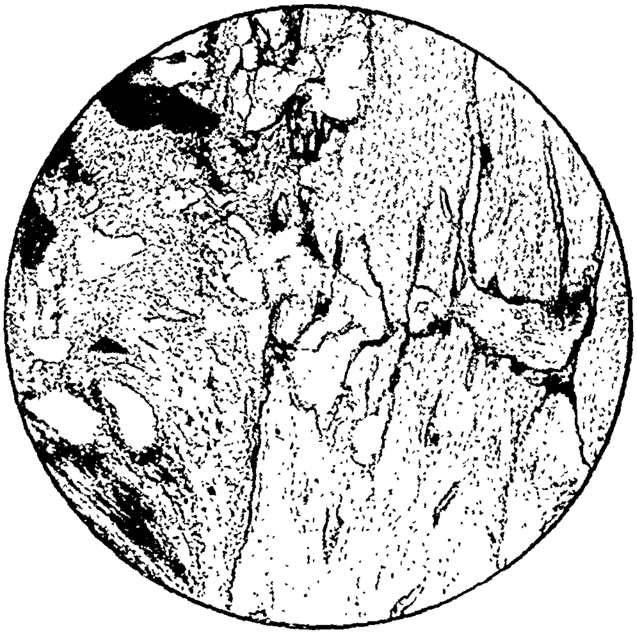

Fig. 3.—Transplant into soft parts, 199 days old, showing some absorption but no substitution by new bone.

If necrotic bone is studied according to this same classification, marked differences will be seen between its behavior and that of necrotic soft parts. These differences are observed chiefly in the manner of removal and in the substances which replace the necrotic material. This is because of the calcareous nature of the bony stroma. The soft parts of the bone, that is, the bone-cells and the contents of the vascular canals and porous spaces, break down and are absorbed in the same way as necrotic soft parts in other portions of the body. The stroma, 60 per cent. of which consists of calcium salts, resists the ordinary rapidly acting lytic agents, persists for a long period and requires a special process for its removal. Comparatively little is known of the chemical process by which bone is absorbed, but according to Wells it varies directly in proportion to the carbon dioxid content of the surrounding media and cells. There has been a general misconception as to the nature of the osteoclasts or cells which produce the absorption. Most of them are ordinary fibroblasts and in the absorption of aseptic necrotic bone but few giant-cells are to be seen. In septic processes, however, large numbers of giant-cell osteoclasts are found.

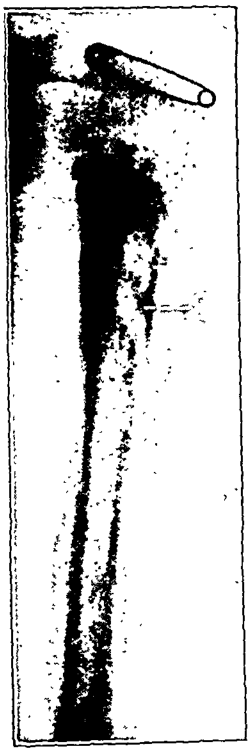

Fig. 4.—Extensive osteomyelitis of humerus with marked involucrum formation and only a small sequestrum (s) at upper end.

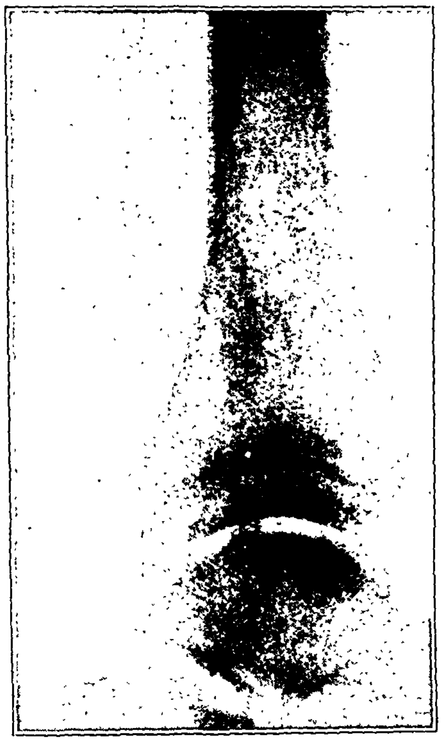

Fig. 5.—Osteomyelitis of fibula showing involucrum and some rarefaction of old cortex.

Necrosis due to circulatory disturbances is best exemplified by bone transplants. When living bone is transplanted, the nutritional disturbances are so great that only the unossified peripheral portions, that is, the periosteum and medullary contents, and the more superficially located osseous cells, survive. The great bulk of the compact bone undergoes necrosis. The fate of the necrotic portion varies with the location of the transplant according to Roux's law of functional adaptation. If the transplant is placed in a bony defect where it has a function to perform it undergoes the following transformation: The surviving osteogenetic cells proliferate, revascularization of the haversian canals occurs, the old cortex is gradually absorbed and replaced by new bone. This is the so-called creeping substitution which was first pointed out by Barth. Figure 1 shows the transformation in a transplant at the end of 164 days. About one-half of the necrotic bone has been absorbed and replaced by new. Figure 2 is a high-power view of the same. If the transplant is placed into the soft parts where it has no function to perform, the surviving portions remain inactive, producing only a very small amount of new bone, no transformation of the transplant occurs, and the necrotic cortex is slowly absorbed by the surrounding connective tissue. This is illustrated in Figure 3, of a 199 days' old transplant.

In the transformation which goes on in aseptic transplants, deposition of new bone keeps pace with old bone absorption, so that the newly formed bone is as dense as the original.

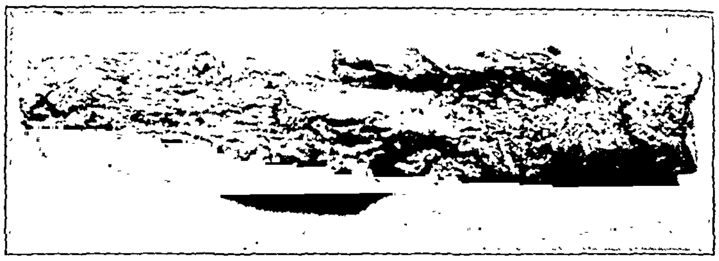

Fig. 6.—Excised shaft of fibula shown in Figure 5. Note involucrum and sequestrum.

Necrotic bone due to infection undergoes a variety of changes according to the cause.

OSTEOMYELITIS

In osteomyelitis the inflammatory process invades the bony cortex resulting in exudation, thrombosis in its nutrient vessels, superficial accumulation of an exudate and necrosis of a varying amount of the shaft, depending on the severity of the process. The changes which the necrotic portion may undergo are variable. In the region where the inflammatory process is severest, the bone is so extensively damaged that it becomes separated from the surrounding portions as a sequestrum. It may be cast off through a fistulous tract by the action of granulation tissue and an exudate; it may be encased by an involucrum and keep up a discharging sinus, or it may be gradually absorbed by the surrounding granulations. In case absorption occurs rather rapidly the place of the sequestrum may be filled

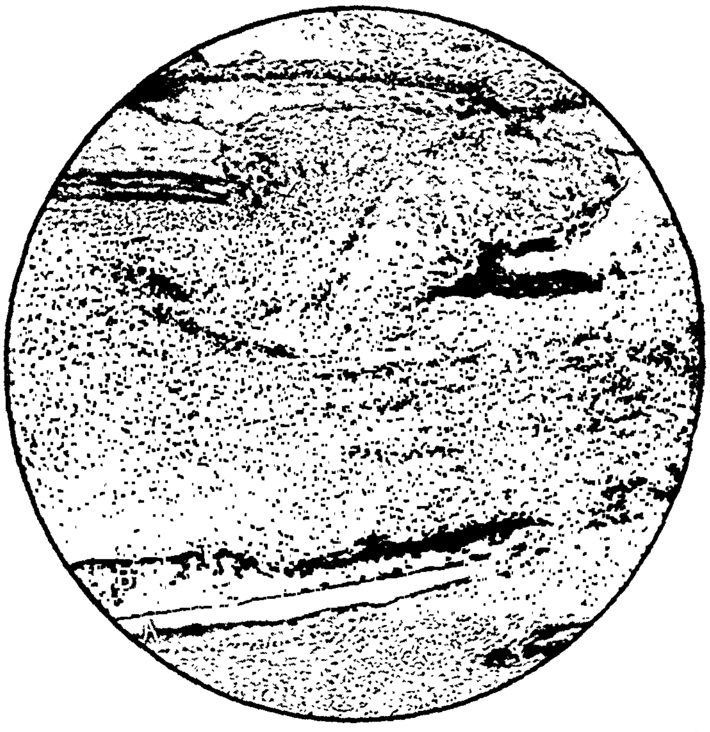

Fig. 7.—Dead cortex in bone shown in Figure 6 away from sequestrum, undergoing absorption and substitution by spongy new bone.

in by new bone, but if the process extends over a long period marked osteosclerosis of the walls occurs, the cavity does not fill in, and a chronic bone abscess results. This sclerotic condition of the walls preventing filling in of the cavity is the explanation of many fistulas which persist after sequestrotomy.

Necrotic bone in which inflammatory reaction is not so severe does not become separated as a sequestrum. The inflammatory signs in it gradually subside. Bloodvessels and granulations containing osteogenetic cells grow into the canals from the surrounding involucrum, absorb the necrotic portions and deposit some new bone, thereby transforming the necrotic into a living area. This transformation differs materially from that which occurs in aseptic transplants, in which as much new bone is deposited as old bone is absorbed. In the substitution of the quiescent necrotic portions in osteomyelitis, absorption is much more rapid and extensive than new bone formation; consequently during the early stage the newly transformed portion is spongy in character. In some of the milder cases of osteomyelitis none of the necrotic bone is separated as a sequestrum, all of it being gradually invaded and replaced by new bone. This accounts for the fate of much necrotic bone which according to Roentgen findings is seen to exist, but which is not cast off as a sequestrum, or removed by operation. Figure 4 is of a suppurative osteomyelitis 3½ months old, with an extensive involucrum along the shaft suggesting considerable necrosis of the cortex. At operation only a small sequestrum was found at the upper end, after the removal of which the patient went on to recovery. No doubt the necrosis was more extensive than this and some of it underwent substitution.

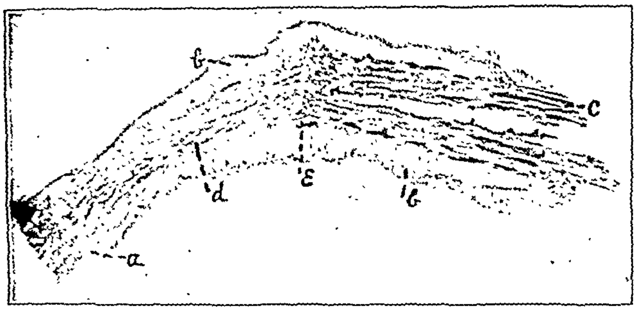

Fig. 8.—Infected transplant with healed fracture through middle portion: *a*, union between transplant and shaft; *b*, involucrum about transplant formed from its periosteum; *c*, sequestrum of upper end of transplant; *d*, dead cortex being absorbed; *e*, fracture in transplant.

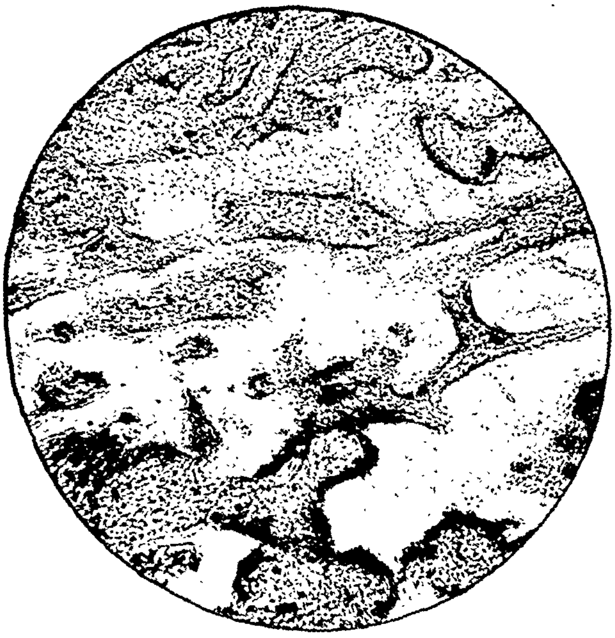

Fig. 9.—Showing rapid absorption of dead cortex with some substitution by new bone.

Figure 5 is of a suppurative osteomyelitis of the lower end of the fibula 2½ months old. There is an extensive involucrum about the diaphysis, a sequestrum of the lateral portion of the cortex, and some rarefaction of cortex on the mesial side. The entire diaphysis including involucrum which was excised by the surgeon is shown in Figure 6. On longitudinal section the mesial side presented no sequestra, but microscopic examination shows a part of its cortex to be necrotic. Rapid absorption is occurring with the deposition of a much smaller quantity of new bone, the ultimate result of which would have been a renewed cortex of spongy bone. Figure 7 shows the combination of dead bone absorption and new bone formation which is going on.

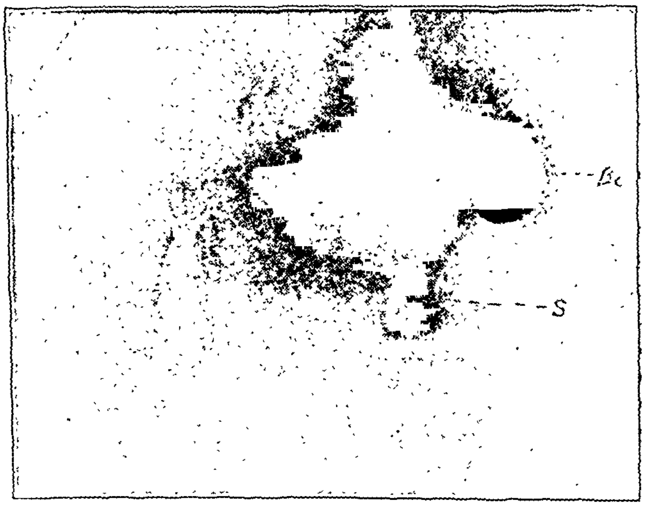

Fig. 10.—Calcified sequestrum casting heavy shadow in tuberculosis of knee. *S*, sequestrum. *Bi*, bismuth paste.

INFECTED TRANSPLANTS

Infection of a transplant may produce various results. If it is severe and involves the entire field of operation, death and sequestration of the entire transplant results, which necessitates its removal. However, if the infection is mild or confined to one end only, a very different condition results. The transplant in most of its length takes, but an osteomyelitis is set up in it, resulting in marked proliferation of the superficial cells which survived, the formation by these cells of an involucrum about the transplant, and rapid absorption of its compact bone, with some new bone formation, producing the type of transformation in the cortex already seen in the necrotic bone of osteomyelitis. In case one end of the transplant is severely infected, it may be separated as a sequestrum and require removal. Such a 75 days' old infected transplant into the ulna of a dog is shown in Figure 8. (There is marked infection and non-union at the upper end where a sequestrum 1.5 cm. had formed.) The rest of the transplant, which has a united fracture through its middle portion, shows osteomyelitic changes. There is an involucrum about it, and marked absorption of the necrotic cortex is occurring with only a small amount of substitution, as shown in Figure 9. This shows that clinically a transplantation may be successful even in the presence of an infection.

TUBERCULOSIS

Most bone destruction in osseous tuberculosis is by caries, in which the dead tissue is absorbed as rapidly as it is formed. More or less extensive areas of necrosis develop either as a result of rapid tissue invasion and caseation in a severe process, or by the formation of a cone-shaped infarct from the plugging of the arterial supply to the involved region. Whether the vascular obstruction is due to embolism, as originally asserted by König, to obliterating endarteritis, or to the ingrowth and pressure of the tuberculous tissue is a disputed point. In any event the infarcted area becomes infected and its medullary space is filled with caseous material. It is separated into a sequestrum from the surrounding living bone by a zone of tuberculous granulation tissue.

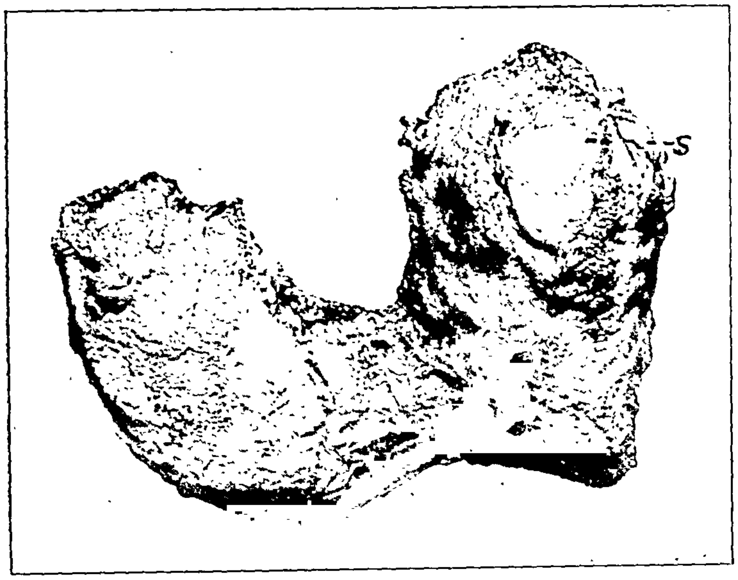

Fig. 11.—Excised condyles of bone shown in Figure 10. *S*, base of sequestrum.

The subsequent changes which such an area undergoes are variable and differ much from those occurring in necrotic bone in osteomyelitis. In some instances tuberculous granulation tissue invades the sequestrum and breaks it down into bone sand, which is either discharged or eventually absorbed, leaving a cavity in the end of the bone bordering on the articular surface or epiphyseal line and filled with granulations or with an exudate and which later is rarely filled out by new bone. In others the sequestrum may become encapsulated and remain undisturbed for months or years, although such an area is apt to contain a certain amount of tuberculous granulation tissue. A sequestrum of long standing casts a heavier shadow than the surrounding living bone. This is partly due to the fact that it is formed early in the disease when the bone possesses its normal density, and that subsequently as a result of the presence of the tuberculous infection and disuse, marked atrophy occurs in the surrounding living bone. Some of these sequestra, however, cast heavier shadows than the corresponding bone on the well side, and the normal arrangement of trabeculae is obscured. Cheyne states that this is due to early new bone formation in the involved area before necrosis sets in. Histologic examination reveals three specimens of which I have made an entirely different explanation. The sequestra contained about the normal amount of trabeculated dead bone, but there was more or less *extensive calcification* of the necrotic material filling the marrow spaces, which is the explanation of the increased density.

Figure 10 shows a cone-shaped area in the region of the external condyle of the femur casting a heavy shadow. Figure 11 is a photograph of the specimen removed by Dr. Dean Lewis at operation. Figure 12 shows a section passing through the markedly atrophic living bone, the zone of tuberculous granulation tissue and the dense sequestrum. Figure 13 is a photomicrograph of the sequestrum showing necrosis of both bone and articular cartilage, and marked calcification of the necrotic tissues filling the marrow spaces. Figure 14 shows the heel of a boy with tuberculosis of the right ankle of three years' standing. A large sequestrum is seen in the os calcis which on comparison casts a much heavier shadow than the well bone on the opposite side. Histologic examination of the removed portions showed extensive calcification in the marrow spaces.

This phenomenon has been noted by other observers, but extremely scanty mention is made of it in the literature on the pathology of bone tuberculosis. I am convinced from these histologic examinations and from a number of roentgenograms of tuberculous joints showing similar dense infarcts from which no tissues were removed that it is of not infrequent occurrence. I have not seen and find no record of calcification occurring in necrotic bone, the result of other diseases. The effect of calcification on the sequestrum, as in the calcification of other diseased foci, is to render it less harmful, so that it must be regarded as a reparative process. If the surround-

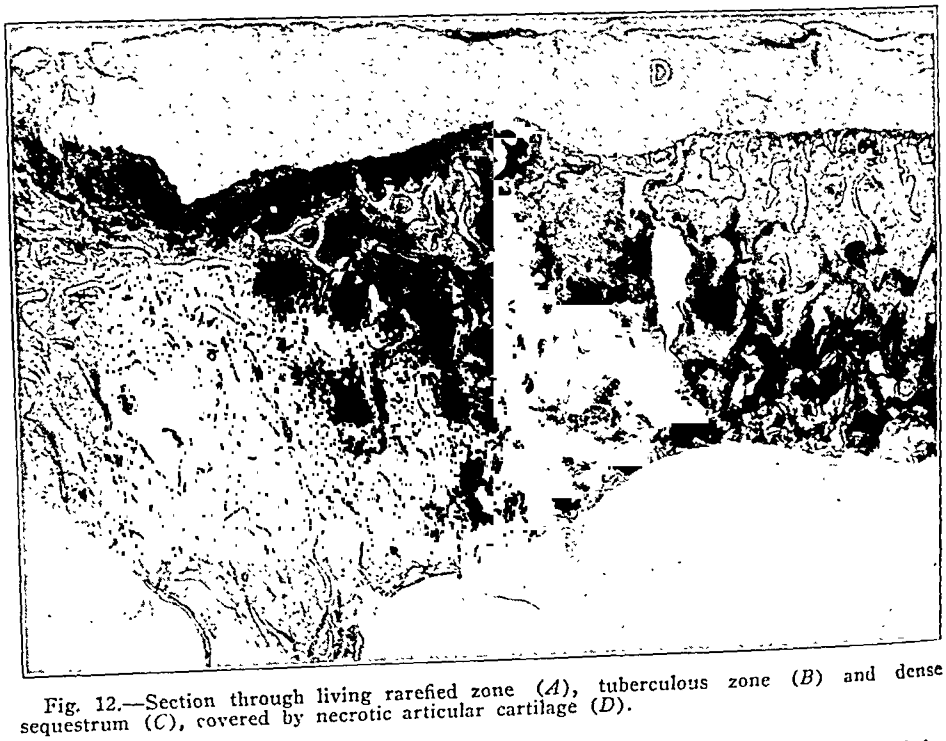

Fig. 12.—Section through living rarefied zone (*A*), tuberculous zone (*B*) and dense sequestrum (*C*), covered by necrotic articular cartilage (*D*).

ing zone of tuberculous granulation tissue should disappear, substitution of the sequestrum by the ingrowth of the surrounding bony tissue would be certain to occur, because the presence of calcium salts either in the shape of a calcified area or as dead bone favors the occurrence of ossification. Calcified areas in the soft parts as the lungs, kidneys, heart-valves, etc., usually undergo a certain amount of ossification by heteroplastic bone formation from the surrounding connective tissue. Whether such substitution of calcified tuberculous sequestra ever occurs has not been recorded, but it is rendered doubtful by the histologic examinations I have made. In all three cases a narrow but distinct zone of tuberculous granulations separated the sequestrum from the surrounding living bone, and as long as such tissue is present, substitution by new bone cannot occur.

From a pathologic point of view the surgical removal of such areas is as clearly indicated as the removal of sequestra in osteomyelitis, for destruction by the surrounding granulations is much more difficult after calcification has occurred than before. Whether clinical results justify their removal is a disputed question with the operating surgeons on one side and the conservative orthopedists on the other.

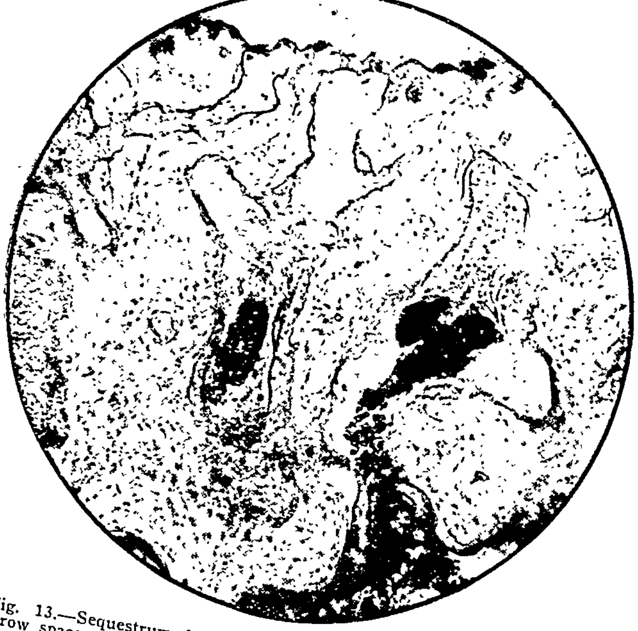

Fig. 13.—Sequestrum by high power, showing calcification in the marrow spaces.

SYPHILIS

In syphilis of the bones where the diaphysis is chiefly affected, caries plays an important part in the bone destruction, but the occurrence of irregular sized and shaped areas of necrosis is much more prevalent than in tuberculosis. They are due to the rapid development and irregular spreading of gummatous material with marked involvement of the blood-vessels and subsequent necrosis of the granulomatous tissue. New bone formation with sclerosis of the surrounding region occurs. Subsequent extension of the infectious process may result in death of the sclerotic portion, so that sequestra may be markedly eburnated.

The fate of the necrotic bone is variable. Much of it becomes separated as sequestra which are absorbed, leaving irregular areas filled with gummatous or necrotic material. When abscess formation and perforation occur, sequestra may be expelled, which is particularly the case with syphilis involving the bones of the vault of the skull. Substitution of the less severely involved necrotic portions may occur by the ingrowth of blood-vessels and osteoblasts from the surrounding living portions with the absorption of the old bone and deposition of new. Figure 15 shows this process occurring about the edge of a large syphilitic necrotic portion of the frontal bone in a man who died of gummatous meningitis.

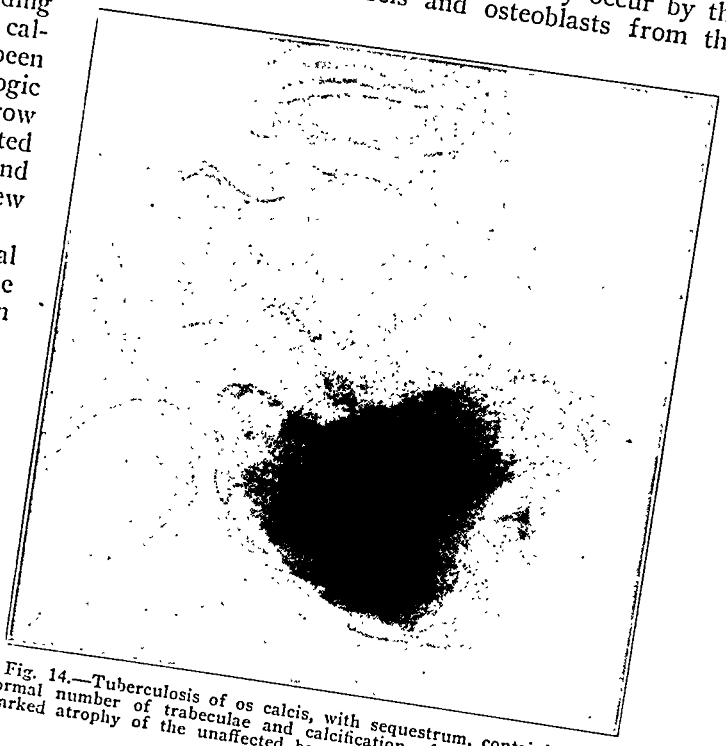

Fig. 14.—Tuberculosis of os calcis, with sequestrum, containing about normal number of trabeculae and calcification of the marrow spaces. Marked atrophy of the unaffected bones.

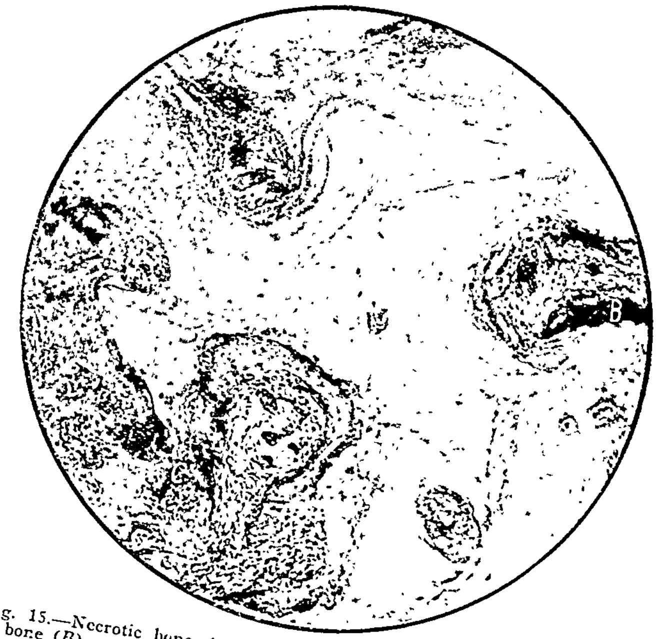

Fig. 15.—Necrotic bone (*A*) in syphilis, undergoing substitution by new bone (*B*).

In conclusion, necrotic bone may undergo a variety of changes—rapid absorption, sequestrum formation, creeping substitution by new bone, or calcification —according to the nature and severity of the cause. Hence, as Axhausen has previously pointed out, the terms necrotic bone and sequestrum should not be used synonymously.

122 South Michigan Avenue.

ABSTRACT OF DISCUSSION

Dr. **Fred H. Albee**, New York: Did the case of the sequestra in the knee shown by Dr. Phemister prove to be one of purely tuberculous infection, without any sepsis?

Dr. **Charles A. Parker**, Chicago: Dr. Phemister brought out a practical point with regard to the possibility of a necrosed bone's being taken care of by the system of the patient. I have seen a case in a child with necrosis of the left tibia and the right femur. Both showed the same appearance, with calcium deposits around, although no involucra. The tibia was removed because the leg still had the fibula for support. The femur was not removed. The patient did very well; and a roentgenogram showed a condition approaching normal a year later. The case was discussed at a medical meeting in Chicago at which many roentgenograms were shown. I asked the surgeons what was done to the femur, because they had strongly advocated removing the bone right away. They told me that the femur did not seem to do so badly as the tibia. The fact is that, in children, these cases may repair themselves, if given the opportunity.

Dr. **Henry W. Frauenthal**, New York: Was the Wassermann test made in Dr. Phemister's last case or in the other two cases?

Dr. **D. B. Phemister**, Chicago: Answering Dr. Albee, there was no secondary infection in any of these cases with tuberculous infection and the formation of sequestra. If the sequestrum is surrounded by an active tuberculous process, it may break down and be removed. The tuberculous process about it may become quiescent and the sequestrum remain; and when that occurs, if calcification takes place in the sequestrum, I do not see why it could not remain forever, and not require removal. In my third case, however, in which calcification of the sequestrum occurred, there was a zone of tuberculous granulation tissue about the shadow. The process had not become quiescent. It acts as a foreign body, and when once calcified it is destroyed with more difficulty by the tuberculous granulation tissue than before. Therefore, its removal seems indicated. I cannot say whether the Wassermann test was made in all these cases or not. I am sure it was in the last; but about the other two, I am not positive.

Bullets and Bacilli.—In the wars of the world they have been as Saul and David—the one slaying thousands, the other tens of thousands. I can never see a group of recruits marching to the depot without mentally asking what percentage of these fine fellows will die legitimate and honorable deaths from wounds, what percentage will perish miserably from neglect of ordinary sanitary precautions?—Sir William Osler, *British Medical Journal.*

COXA VARA ADOLESCENTIUM TRAUMATICA *

ARTHUR STEINDLER, M.D.

DES MOINES, IOWA

My remarks are to be confined to those cases of coxa vara of the adolescents in which a causative or contributary relation exists between trauma and deformity.

In a general way it is now conceded that separation of the upper epiphysis of the femur is likely to occur from trauma, either as partial or as complete separation or decollement of the epiphysis. For practical purposes, however, much of the information drawn from literature is too casuistic and dogmatic. On the other hand, considerable work has been done to establish definite facts in regard to practical questions of etiology and diagnosis. For instance, what is not only possible but likely to result from certain trauma to the hip in certain ages? What amount of violence is necessary to produce gross changes in the adolescent hip? What is the influence of chronic or repeated traumatism? And what is known of the relation hereto of static forces and rachitic predisposition?

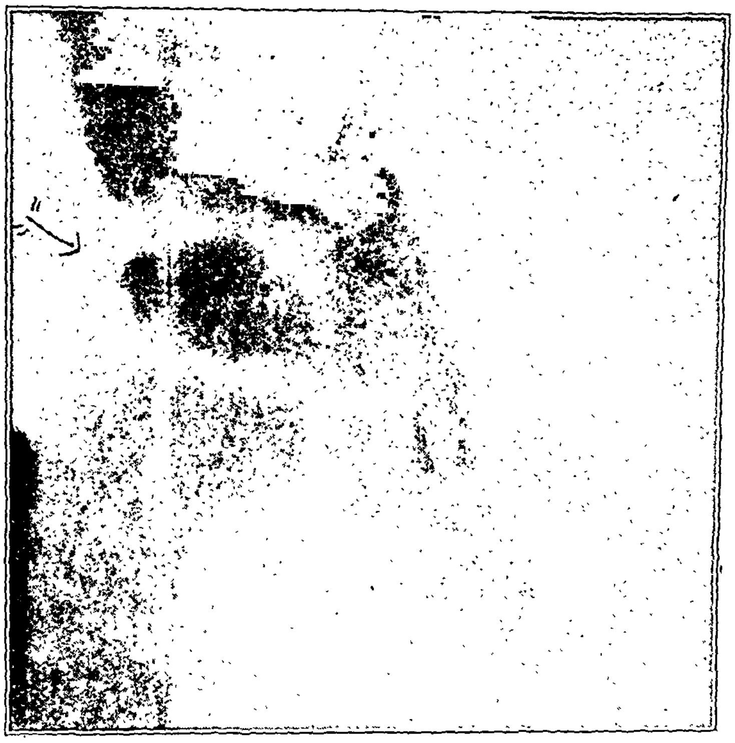

Fig. 1.—Traumatic separation of the epiphysis with partial atrophy of the head (Case 1).

Early investigations into the problem of adolescent coxa vara, beginning with the observations of Mueller, Hofmeister and many others are greatly governed by two points, late rickets and static forces. Concerning the latter, Helbing,[1] in a very exhaustive monograph on the subject, emphasizes the difficulty of distinguishing between the static and the traumatic coxa vara adolescentium, except for minute data in the history; but as I shall show later, especially the data bearing on the traumatic nature of the disease often fail to come forth in the history of the patient.

It is probably equally difficult to establish the relationship between trauma and late rickets. Among the endeavors which have been made to arrange the material from this point of view I may mention Peltesohn's[2] classifications:

1. Cases of traumatic coxa vara without rickets, which he thinks are rare. Nevertheless the literature abounds in instances of epiphyseal separation and following deformity in which no traces of rachitis could be found.
2. Cases of rachitis of the upper end of the femur with trauma as contributing cause of coxa vara. To

[2] Peltesohn, S.: Zur Aetiologie und Prognose der Coxa vara infantum, Ztschr. f. orthop. Chir., 1911, xxviii, 3, 4.

this group undoubtedly belongs a majority of cases of traumatic separation of the epiphysis.

3. Purely rachitic cases of coxa vara adolescentium without trauma, but as the writer himself hesitatingly remarks, it may be that in these cases, too, slight traumatism contributes to establish the deformity. It seems that more satisfaction is to be derived from the simple anatomic distinction of Froelich[3] and other French writers: coxa vara trochanterica, coxa vara cervicalis and coxa vara capitalis. They consider the depression and inflexion confined to the neck as rachitic, while the depression of the head alone on the neck in this age, the coxa vara capitalis, is traumatic, meaning epiphyseal separation or infraction. As Froelich terms it, coxa vara essentielle, from overweight or insufficiency of the epiphyseal cartilage. Kirmisson,[4] too, points out that the *decollements epiphysaires* in adolescents are clinically and radiologically established beyond doubt as following insignificant injuries and leading to coxa vara deformity. These observations are now rapidly being acknowledged and confirmed from many directions. They are by no means rare. In 1903 Hoffa[5] reported 53 of his own cases, besides the 10 of Royal Whitman,[6] all in all 88 cases in the literature of separation of the epiphysis. Lately Wolff[7] reported 34 cases and Gerstle 53 cases of the same nature.

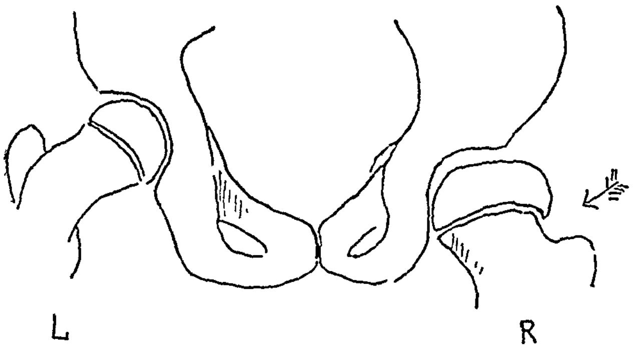

Fig. 2.—Epiphyseolysis following acute epiphysitis (Case 2).

Relative to predisposing rickets, the enlargement of the epiphyseal line and its softening as studied by Mueller, Kocher, Hofmeister, Frangenheim and a host of others indeed furnishes a favorable condition for slight and apparently insignificant injuries to loosen or to displace the head of the femur in the epiphyseal line. From Roentgen studies of such cases Siebs[8] arrives at the same conclusion, that most cases of coxa vara traumatica of the adolescents are primary separations of the epiphysis, at least as far as the coxa vara capitalis is concerned; that furthermore, if rachitic softening preexists it is manifest by the curving of the neck (coxa vara cervicalis) and it may represent a predisposing factor for following epiphyseal separation on slight trauma. While this combination is the rule, cases of purely rachitic deformity and cases of pure traumatic nature do exist, according to this observer.

On the other hand, the ambiguity of the relations of coxa vara adolescentium traumatica to statica is best illustrated by those cases in the literature classified as traumatica and following fall on the hip or other minor injuries (Rammstedt[9]). Sprengel[10] remarks that this epiphyseal displacement varies very widely in degree. The more incomplete forms approach more and more the so-called static form.

A gross displacement of the fragments necessitates a more extensive laceration of the periosteal covering. Cases occurring from major injuries show correspondingly more of periosteal tear. But the majority of cases occur from lesser injuries, as fall on the hip, etc., and in these cases the epiphysis may give as the point of lesser resistance while the periosteum still is complete. Microscopic examinations of the epiphysis after separation were carried out by Sprengel. Though unable to find any other bone pathology in his cases he noticed that the interfragmental substance consisted of true callus tissue. In the callus itself he found besides minute hemorrhages numerous very small particles of detached necrotic bone tissue and cartilage proving the traumatic nature, although no mention was made of a trauma in either of his two cases.

The Roentgen-ray evidence of the simple displacement offers no difficulty. But secondary changes may be noticed also consisting in atrophy of the femoral head and corresponding points of the acetabulum. R. Levy's[11] investigations show that osteo-arthritic changes may follow disturbances of the epiphyseal lines and that a coxa vara capitalis osteo-arthritica may be seen as a sequela of traumatic separation of the epiphysis.

Experimentally separation of the epiphysis has been obtained by Wullstein and Rammstedt. They were able to produce it by direct violence to the trochanter with the pelvis fixed and the thigh in extension and slight abduction. They conclude from their experi-

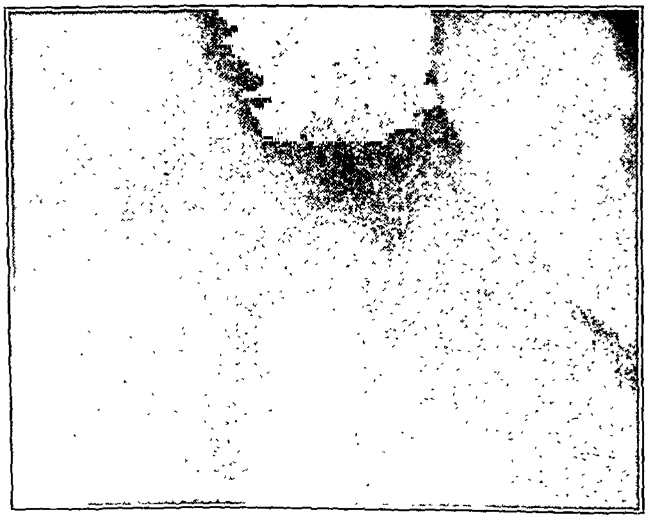

Fig. 3.—Coxa vara traumatica from separation of the epiphysis (Case 9).

ments that the femoral epiphysis, while quite firm and resistant, will under certain conditions yield to either total separation or partial loosening according to whether and to what extent the periosteal covering is being torn. The periosteum may hold the head in place even after separation, and this point is considered explanatory of the fact that the young patient after the injury does not lose the function of the limb, but is able to bear weight on it. Only step by step the loosened epiphysis yields under the body weight as the tears in the periosteum allow of the slanting of the head downward and backward.

With all this evidence brought out statistically, pathologically, radiologically and finally experimentally in favor of the existence of the epiphyseal separation and its relation to coxa vara adolescentium, it may seem that I am wasting too much time discussing undisputed facts. But the point is not so much to prove the condition as such, but rather its relative frequency. In other words, in a certain age, from say 9 to 16, if a certain traumatic factor, major or lesser, is given, epiphyseal separation is not only possible but highly probable to occur, with or without preexisting or coexisting rickets, and to be followed by a deformity known as coxa vara adolescentium. In fact, such was the case in eighty-four out of Hoffa's eighty-eight cases collected.

The second point is that the producing trauma may be and very often is so slight as to fail to impress the observer with its significant connection. Nevertheless, as already stated, minor injuries and especially repeated ones are perfectly capable of producing the separation. Static influence, too, is a continuous strain. The late establishment of the deformity after strain or injury have ceased to assert themselves offers a striking analogy to the posttraumatic kyphosis of Kuemmel, especially since so-called molecular necrosis of detached bone and cartilage have been found microscopically in cases of traumatic coxa vara adolescentium.

In the third place, the loss of function in these cases is never absolute or immediate, except in cases of great violence or injury. In fact, in most cases there is a period of functional integrity, the impairment following later and slowly according to the progress of the deformity.

Among approximately 1,000 orthopedic cases I have found traumatic separation of the epiphysis either clinically or radiologically or both, in ten cases, equaling 1 per cent. Short abstracts of the histories follow:

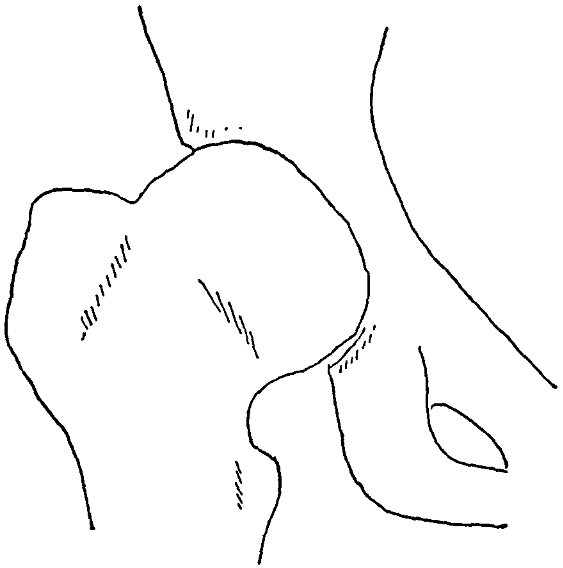

Fig. 4.—Coxa vara deformity, probably following epiphyseal separation (Case 10).

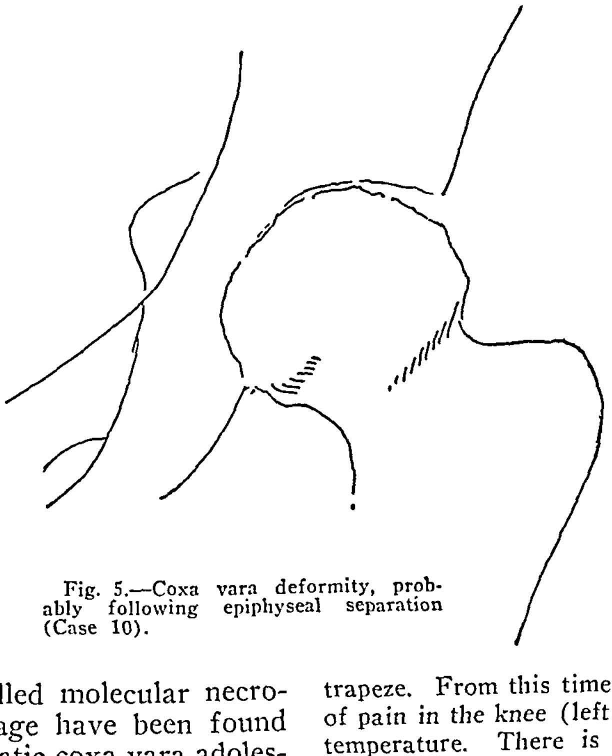

Fig. 5.—Coxa vara deformity, probably following epiphyseal separation (Case 10).

Case 1.—J. J., aged 12. March, 1913. No trauma given. Complains of pain in right hip and limp for four weeks. Increasing disability. No night cries, no temperature. There is restriction of abduction and inward rotation. The Roentgen ray shows traumatic separation of the epiphysis with partial atrophy of the head (Fig. 1).

Case 2.—E. G., aged 11. April, 1914. A few months ago sore throat followed by pain in right hip. Confined to bed for three weeks, when symptoms subsided. After getting up a limp gradually developed. No night cries. Hip partially fixed in adduction and outward rotation. Abduction nil, inward rotation very limited, flexion free, extension limited. Roentgen ray shows slight displacement of right epiphysis. Diagnosis, epiphyseolysis following acute epiphysitis (Fig. 2).

Case 3.—C. F., aged 13. March, 1914. Slight trauma two months ago (fall on right hip). Suffered no loss of function. Pain and limp developed gradually in the last few weeks. Increasing shortening. No night cries, no temperature. Right hip in adduction. Abduction nil, adduction free, out and inward rotation free. Roentgen ray shows slight epiphyseal detachment. Diagnosis, traumatic separation of the epiphysis. Spica and crutches.

Case 4.—L. P., aged 19. March, 1914. Limped with right limb for a number of years, does not know how long. Deformity increasing. No trauma given. Hip in adduction. Abduction slightly restricted, inward rotation considerably so. Outward rotation normal, extension and flexion slightly restricted. Roentgen ray shows coxa vara deformity with overlapping head of the femur. Diagnosis, coxa vara capitalis, statica (?). Operative correction advised.

Case 5.—P. K., aged 9. April, 1914. History very incomplete. Has been limping for a year or so. No pain, no night cries. No trauma. Hip in adduction and eversion. Abduction restricted, all other directions appear to be free. No temperature. Roentgen ray shows slight epiphyseal displacement with partial absorption of the head. Diagnosis, separation of epiphysis, secondary atrophy (epiphysitis?).

Case 6.—L. E., aged 9. November, 1913. Has been limping since last July after a fall out of a trapeze. From this time he also has complained occasionally of pain in the knee (left). No pain in hip, no night cries, no temperature. There is slight restriction of abduction and flexion abduction. More restriction of extension. Slight atrophy. Roentgen ray shows some epiphyseal displacement and signs of absorption. Diagnosis, coxa vara traumatica with posterior separation of epiphysis.

Case 7.—V. M., aged 11. December, 1913. Was hurt two months ago while playing by being pulled violently by his right limb and stepped on on the right hip by one of his playmates. He was lame for three days but after that he managed to go to school. He again complained of pain in right knee and thigh soon afterward. There was also pain in the small of his back. At that time he was very restless but is better now. No night cries. Gradual impairment of function. At time of examination does not bear weight on his limb at all but walks on crutches with the limb drawn up. There is tenderness over the right sacro-iliac region and in front of the thigh and very distinctly in the gluteal region and over the greater trochanter. There is no distinct restriction of motion. The Roentgen ray shows a separation of the head ¼ inch and about the same in the apophysis of the greater trochanter upward. Diagnosis, traumatic separation of epiphysis and trochanter major. Plaster spica and crutches.

Case 8.—M. M., aged 14. May, 1912. Had a fall December last, landing on his back and left hip. After a free interval of three weeks he developed a limp and some soreness of left hip, but no nightly pain. He was put to bed for two weeks and the limp disappeared. After he got up he started to limp again, which he has done to the day of examination, the disability becoming gradually worse. The left thigh is in adduction. Motion is limited in abduction and inward rotation. No actual shortening. Trendelenburg symptom positive. The diagnosis coxa vara traumatica from epiphyseolysis is confirmed by the Roentgen ray.

Case 9.—Mrs. S., aged 29. December, 1912. When 3 or 4 years old she had a fall, injuring the right hip. As far as she remembers there was a gradual drawing of the hip and an increasing limp, shortly after the accident, but no severe or nightly pain. Was always able to bear weight on the hip, but complains more for the last six months. The hip is incompletely fixed in adduction flexion position, abduction and inward rotation being completely abolished, while the other directions are comparatively free. The real shortening is only ¼ inch. The diagnosis is coxa vara traumatica from separation of the epiphysis. No roentgenogram could be taken (Fig. 3).

Case 10.—V. P., aged, 16. April, 1913. October last he slipped and fell on his left hip, but was not disabled for two weeks. Then he began to get worse, complaining of pain and limping and was put to bed for three weeks. Though he regained the function of his leg, the limp has been steadily increasing, also increasing shortening. There is considerable adduction contraction with outward rotation, and limitation of abduction and inward rotation. The other directions comparatively free. The Roentgen ray shows coxa vara deformity, probably following epiphyseal separation (Figs. 4 and 5).

REVIEWING THE POINTS SIGNIFICANT FOR THE DIAGNOSIS

Injury to the hip of moderate extent, fall or wrench.
An intermediate period of functional freedom.
No or very mild subjective symptoms.
The late and gradual development of the coxa vara deformity with increasing disability.
The age of the patient.

I do not think that absolute reliance can be placed on the Roentgen-ray evidence, inasmuch as very slight lesion will not show any more than they do in injuries to the spine which are later followed by Kuemmel's posttraumatic kyphosis. Still it is an invaluable aid.

Memory and Education.—Memory is a fundamental phenomenon of organic life. In its widest sense it signifies the fact that impressions once received by an organism are retained for a greater or less period and that this retention is indicated in the modified behavior of the organism. The evidence of memory in animals is their ability to profit by experience. A white rat is placed at the entrance of a maze at the center of which is food. The animal moves about in an aimless manner until at length it reaches the center. If on succeeding trials the rat shows an improvement in the accuracy and rapidity with which it moves about the maze, this means that its earlier attempts have in some sense left their effects; they have modified in subsequent conduct. Memory, when used in this widest sense of the term, lies at the basis of all learning. It is a measure of educability.—Solvin.

COXA VARA*

JOHN RIDLON, M.D.

CHICAGO

Perhaps the most valuable paper that has ever been written on coxa vara is that of Elmslie,[1] which appeared in 1913.

For the sake of giving Elmslie's views a wider circulation it has seemed to me better to make this paper a review rather than attempt a personal paper on the same subject. Elmslie says:

> Coxa vara is an anatomical term indicating the condition of depression of the neck of the femur, so that the angle that the neck of the femur makes with the shaft, normally about 125 degrees, is lessened. Such depression of the neck of the femur may occur by bending at the root of the neck, in the middle of the neck, or close up to the head of the bone, or there may be a general curvature of the whole neck.
>
> The clinical manifestations of coxa vara are, briefly, diminution in the degree of abduction permitted at the hip-joint with real shortening, manifested by elevation of the trochanter. Several other conditions occur in which these clinical manifestations are found, but in which the radiographs show a deformity of the head of the femur rather than a depression of the neck. These are best excluded from coxa vara; they are: (1) results of old inflammatory disease, either acute, such as epiphysitis or chronic, as tuberculous disease; (2) osteo-arthritis, and (3) pseudo-coxalgie (Clave).
>
> Even though we limit the name coxa vara to an actual depression of the femoral neck, we are still left with an anatomical condition which may vary in different cases, and which may result from different pathological processes. The pathology of some of the forms of anatomical coxa vara is clear and needs but very brief allusion. These conditions can be included under two headings: (1) injury; that is, fracture of the neck of the femur, with union in a deformed position; (2) processes in which the bone is known to be definitely softened and to give way under pressure; i. e., rickets, osteomalacia, osteitis deformans, osteitis fibrosa.
>
> To these groups I shall not allude further except that the pathology of the idiopathic varieties of coxa vara is intimately connected with the question of the occurrence of fracture of the femoral neck in children, and that it is necessary to include a brief description of the anatomy of rickety coxa vara. We are left with idiopathic cases of coxa vara, which may be classed according to their history and anatomy into three groups: (1) congenital; (2) infantile or cervical (*a*) with a fibrous intersection in the neck, (*b*) with a strong neck without any fibrous intersection; (3) adolescent, and possibly a few aberrant cases which do not fall properly into any of these groups.

I have not been accustomed to consider any cases as true coxa vara when the pathology was as stated above, but have limited the use of the term to a giving way of the epiphyseal line between the head and neck to a greater or less extent—an extent sufficient to give sooner or later the characteristic symptoms of coxa vara. That diagnostic symptoms of coxa vara may be present before roentgenoscopy will show a slipping at the epiphyseal line and before any certain shortening can be measured has been demonstrated by Case 1, to be recorded later on.

It is true that most cases of coxa vara appear at about the period of adolescence, but since all cases do not appear at this time and since it has not been shown that the adolescent period is an etiologic factor in these cases, I think it best to dissent from Elmslie's use of the term. The same may be said of injury as an etiologic factor; by no means do we find a history of injury in all cases. I have observed two bilateral cases. In neither were the hips attacked at or near the same time, and in neither of the four hips was there any conscious injury at or about the time that shortening occurred. It is equally true, as Elmslie has noted, that coxa vara is found much more frequently in boys than in girls. We do not say boys' coxa vara, since girls also suffer; and we ought not to call it adolescent coxa vara, since it occasionally occurs at other periods, or traumatic coxa vara, for frequently there has been no known injury. Let us then call it coxa vara, which without qualifying adjective indicates the pathology, and let us clearly separate coxa vara from fracture of the neck of the femur in children and adolescents.

---

* Read before the Section on Orthopedic Surgery at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

[1] Elmslie, R. C.: Coxa Vara, Its Pathology and Treatment, London; Henry Frowde, Oxford University Press, and Hodder and Stoughton, 1913, price 2 shillings net.

Under symptoms and physical signs, Elmslie says:

> A few points in the clinical symptoms of adolescent coxa vara assist us to form views as to the pathology—in the first place whether there is an accident or not there is nearly *always in the progressive stage of the deformity a period* during which the movements of the hip-joint are almost or quite abolished. Hofmeister in his first contribution to the subject laid stress upon this stage, but it seems to have been forgotten by many surgeons, who, on account of the fixation of the joint, make the diagnosis of tuberculous disease of the hip. The rigidity is due entirely to muscular spasm; it disappears when the joint is examined during anesthesia, and its presence is easily understood when it is remembered that the lesion in adolescent coxa vara is close to the epiphyseal line and *that this line is entirely intra-articular.* During this stage there is also *pain in the hip, extending down to the knee, rapid wasting of the muscles of the thigh and buttock,* and a fulness in Scarpa's triangle. These symptoms also are like those of tuberculous disease; they indicate only an intra-articular lesion of the hip-joint.
>
> This period may last a few weeks or several years; sooner or later the movement returns, and the deformity only remains. The limb is now shortened, adducted at the hip-joint, and everted; occasionally also it is a little flexed. The real shortening, measured from the anterior superior iliac spine to the internal malleolus, is seldom more than an inch; *the total apparent shortening,* measured from the umbilicus to the internal malleolus, is *often as much as* 2½ or 3 inches; this and the eversion are usually evident at a glance. The great trochanter is raised to a degree corresponding with the real shortening and is very prominent. *Movements* at the hip-joint are usually in the later stages free, except abduction and internal rotation, which are limited by anatomical factors.

I have always regarded the position of adduction and outward rotation, with abduction and inward rotation limited, as the first typical symptoms of coxa vara. Flexion also will be found restricted, but it will be found that the thigh can be flexed further if somewhat abducted during the movement than if carried upward along the anteroposterior plane. These symptoms and the fulness in the groin may be explained by the course of Case 1, in which unquestionably the epiphyseal line opened up anteriorly some months before the cervical side slipped upward on the caput and a true coxa vara showed in the roentgenograms.

To quote again:

> In acute traumatic coxa vara a definite downward displacement of the epiphysis of the femoral head is seen, the upper part of the fractured end of the neck appearing above as a prominence. In cases following at an interval after an accident, after several slight accidents, or without any accident, the appearances are almost identical and are as follows: The head of the femur is displaced downward, so that the lower part of its joint surface no longer lies in the acetabulum. In spite of the fact that most radiographs are taken with the limb everted, the head does *not* appear unnaturally large; this indicates that it is displaced posteriorly. The epiphyseal line is, as a rule, clearly seen. It appears unnaturally long in some radiographs; this is probably due to the *fact that the head is not seen from its true anterior aspect. Thus, considering the epiphysis as a cup-shaped disk with the concave side toward the neck,* the view includes part of this concave surface. The femoral neck in most cases shows two parts; the part next to the shaft has its natural direction, at any rate as regards its lower border; the upper part, though springing naturally from the trochanteric region, being rounded off above. The part of the neck near the head, however, slopes downward and inward to join it; the lower border here takes as a rule a sharp downward curve like a hook, and below the head overhangs it "like a mushroom." The upper border of this part forms a continuous upward convexity, internally continuous with the surface which faces the epiphyseal line; it shows, however, in many radiographs a prominence varying in size and situated nearly opposite the upper margin of the acetabulum. This, doubtless, is the spot to which the outer extremity of the epiphysis was attached.

After considering the various other forms of so-called coxa vara, Elmslie's conclusions are:

> Coxa vara is a deformity, then, of the upper epiphyseal region of the femur and varies in its anatomy as it comes on: (1) before birth, when a strong neck pointing in an abnormal direction results; (2) during the first five or six years of life, while the neck of the femur is largely cartilaginous, when the depression is at the root of the neck of the femur, with usually a fibrous intersection across the neck; (3) during adolescence when there is a slipping downward and backward of the epiphysis. This deformity is undoubtedly due often to accident; there is a difference of opinion among authors as to whether the more usual accident in childhood is a displacement of the epiphysis or a fracture of the neck; the truth, I believe, is that during the earlier years of life, before there is a well-shaped neck, the accident is a fracture of the neck; later, when there is a well-formed neck and a *transverse epiphyseal line separating it from the head,* the injury *is a separation of the epiphysis.* We find, therefore, *that the coxa vara of young children is cervical in type,* the coxa vara of adolescence is epiphyseal. Accident will *not* account for all cases, but we know that the *non-traumatic* cases have the same pathological anatomy as the traumatic cases occurring at the same age period; we must presume, therefore, that in them there is the same displacement, but that there is no definite injury to produce this, that some local pathological condition of the bone exists which enables such displacement to occur with great ease.
>
> On analogy with such conditions as adolescent genu valgum, on the microscope findings in cases of resected specimens and on the undoubted occurrence of infantile coxa vara in rickety children, we may presume that this pathological condition consists in a defective ossification of the bone formed at the upper epiphyseal line of the femur. As has already been briefly indicated, the occurrence of coxa vara *deformity* alters the direction of the pressure of the weight *of the body* on the neck of the femur. In those cases, such as the congenital, in which there is a strong neck and no displacement of the epiphysis, this altered pressure will not tend to greatly increase the deformity. In the ordinary *type* of infantile case, however, this alteration brings the pressure of the upper margin of the acetabulum directly across that weak part of the neck which contains the fibrous intersection, and in the ordinary adolescent form similarly the pressure of this margin of the acetabulum is brought directly across the region near the epiphyseal line, at which the displacement

of the head of the femur has taken place. As a result, in these two forms of coxa vara, when once a moderate degree of deformity has arisen, there is a mechanical factor in the shape of the weight of the body acting through the acetabulum which will tend to increase the deformity, quite apart from the existence of any pathological process. This mechanical point is of great importance in treatment.

Nowhere in Elmslie's paper do I find that he has noticed that which has been noted by many others, namely, the great frequency with which we find these boys having coxa vara to be fat, and if male of the feminine type, and with underdeveloped sexual organs. All children of this type should be constantly under medical supervision and such preventive diet and drug treatment as seems indicated.

For prevention of the increase of deformity Elmslie recommends the use of the Thomas caliper splint, made long enough to prevent the weight from being transmitted through the hip to the ground. This of course is a most reasonable theory, but as a clinical fact it does not prevent the increase of deformity, nor, as in Case 1, does it prevent shortening when no shortening has yet occurred.

Elmslie mentions forcible abduction during narcosis, but appears to have had but a single experience with a doubtful result. He also mentions the various operations of osteotomy without any evident devotion to any one of them.

I have treated all cases of coxa vara for the past four years by strong traction with the limb abducted, the patient not being anesthetized, and while the limb was held in this position have applied a plaster splint from the ankle to the nipples. I have allowed the patients to lie still or walk about as they might choose; and have continued this treatment until the patient had walked without pain or sensitiveness for at least three or four months.

CASE 1.—This boy, R. R., was just 12 years old, short and weighed 110 pounds. His sexual organs were extremely undeveloped. He began to limp three months before examination after riding a donkey up Mount Vesuvius and climbing the dome of Saint Peter's at Rome. The left leg lay rotated outward. Except to inward rotation all movements at the hip were resisted when carried to their extremes. In flexing the thigh it circled outward. There was no shortening, and the Roentgen-ray pictures were negative. After three more months without material change a long traction hip splint was applied to be used as a perineal crutch. Despite this, at the end of six months there was ¾ inch shortening and the roentgenogram showed a typical coxa vara. The patient was anesthetized, and the leg stretched forcibly and put up in plaster in abduction. For some time the patient remained in bed, then used crutches, and finally walked in the plaster splint without crutches until all evidences of sensitiveness had passed. Somewhat more than a year later there was some sensitiveness in the right hip and some restriction to motion, but no shortening; after six months or more shortening developed, and the roentgenogram showed coxa vara in that hip. Now the hips are practically alike. When he sits with the knees a foot apart the feet cross because of the outward rotation of the thighs.

This case shows conclusively that the epiphyseal line may open up in front, giving outward rotation of the thigh, some months before the neck becomes detached from the head and slips upward into the characteristic relation. And it demonstrates that we are warranted in making the diagnosis of coxa vara when the clinical symptoms of coxa vara are present sometime before the displacement can be demonstrated by roentgenoscopy.

CASE 2.—This case, although apparently typical of coxa vara, is exceptional in my experience. The boy, E. B., fell a distance of 10 feet to the ground nine and one-half months before the picture was made. There was ¾ inch real and 1¼ inches apparent shortening; ¾ inch atrophy of the thigh and ½ inch of the calf; 35 degrees flexion deformity; a small fluctuating tumor on the anterior and outer aspect of the thigh, and only slight motion in flexion and rotation.

CASE 3.—This case, apparently typical coxa vara, is somewhat unusual. The boy, A. P., was 7 years old. He had limped for a year; cause unknown, but had jumped a good deal. There was ⅝ inch shortening, and possibly ⅛ inch atrophy of thigh and calf. Rotation was restricted, but there was nearly full flexion and hyperextension.

CASE 4.—This man, F. M., when a youth worked hard on a farm. He gradually became lame when about 14 years old, and the leg became short. He was taken to a prominent Chicago surgeon, now dead, who said it was not hip disease, and advised stopping work and better feeding. Later he consulted another prominent surgeon of Chicago, also deceased, who asserted that it was tuberculous hip disease and applied an extension splint and crutches. Then pain came in the other hip, and again the diagnosis was tuberculosis, and he was treated in bed with weight and pulley to both legs for nineteen months. At a later period he had another year in bed. Finally in 1911 he was sent to bed again for a year with weight and pulley treatment by one of our noted Chicago surgeons, now living. In January, 1912, this man was brought to me the distance of about one hundred miles on a cot with weights attached to his limbs. There was 1 inch real and 2¾ inches apparent shortening; no atrophy of thigh or calf. There was no rotation and little flexion at the right hip. Roentgenoscopy revealed the left hip normal and the right hip having an ancient coxa vara.

CASE 5.—This boy, C. B., aged 15, began to limp without known cause eight months before I saw him. The limb was adducted and rotated outward. No real shortening but 1½ inches false shortening. There was slight restriction to flexion, and sensitiveness to hyperextension and inward rotation. He was treated with a long traction hip splint for about three years.

7 West Madison Street.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. STEINDLER AND RIDLON

DR. WALLACE BLANCHARD, Chicago: Two or three years ago, I reported two cases of coxa vara before the American Orthopedic Association. In one the condition was clearly inflammatory. It occurred in a boy of 18 or 20 years, who had been very sick with diphtheria and had made a slow recovery. The diphtheritic infection occurred when he was about 12 years old. He was in bed for about a year but gradually recovered. During the succeeding two or three years, nothing unusual was noticed. Then coxa vara slowly developed. The deflection downward was about 120 degrees, with a mushrooming of the heads. I presented, in connection with this case, one of idiopathic coxa vara, in a boy about 14 years of age. He had no history of injury, and had not had any symptoms of rickets; but at about the age of 13 he was noticed to walk somewhat differently, with an incurved back, presenting something of the appearance of a double congenital hip dislocation. This gradually increased. When I saw him the head and neck of each femur were deflected downward about 120 degrees. The deformity was symmetrical in both hips. I asked Dr. Ridlon where he would place it, according to Elmslie's classification; and he said that he did not know.

DR. W. C. CAMPBELL, Memphis, Tenn.: I have had four cases of apparent coxa vara in private work, which later developed into tuberculosis of the hip. All the patients were between the ages of 8 and 10 years, an age at which you would not expect to find a separation of the epiphyses in this region. Roentgenoscopies were made in all the cases; and in none, at first, did there appear to be any changes that we could discern. Later on, however, they showed tuberculous changes in the region of the epiphyses. The symptoms in the early stages when these cases were seen were limitation of internal rotation and abduction. There was very little pain and none of the usual symptoms of tuberculosis of the hip were present. I feel sure from these cases that tuberculosis of the hip may give, in the beginning, the identical symptoms of coxa vara. This did not occur to me until these cases came under my observation about two or three years ago at nearly the same time. The clinical symptoms later, the Roentgen-ray findings and the treatment throughout the whole course of the disease were those of tuberculosis of the hip. They were definite cases of tuberculous hip. I had had other cases of coxa vara, particularly in adolescents and young children; but I had never seen an acute coxa vara at that age, and this made me doubt such a diagnosis though all symptoms and physical *signs pointed to that condition.*

Dr. J. D. Griffith, Kansas City, Mo.: I have had only one case but from the study of that and the literature that I could find on the subject of coxa vara, including the work mentioned by Dr. Ridlon, I came to the conclusion that there was only one solution of coxa vara. It belonged to the domain of metabolism. Here was an area that was imposed on by the body weight; and if, during the course of development, there was not a sufficient deposit of salts in the line of epiphyseal union, as Dr. Ridlon has pointed out, the result could easily be a diminution in the distance between the *trochanter and the head of the femur and a change in its* angulation. In this condition, following an enteroptosis or anything else that might produce an improper metabolism. there might be absorption of the material thrown out; and I think that if we could get at the histology of the metabolic changes, we should find the cause of the trouble. My case was in a child who had no trouble until he commenced to bear his weight, at the age of 3 years. Then he began to have some trouble in his hip. I could not make out, by means of the Roentgen ray, or anything else, any tuberculous trouble; but here was a distinct coxa vara at the age of 8. I then made up my mind that this was due to a metabolic trouble. Only three weeks ago, the patient being still under treatment, he came to my office again and I found that the other hip was commencing to show the same process. I am satisfied that tuberculosis has nothing to do with the condition in this case.

Dr. Reginald H. Sayre, New York: I believe that a great many of these patients, undoubtedly, as Dr. Griffith says, *suffer from a disturbance of metabolism;* and that, as shown by the Roentgen ray, the appearance is not that of tuberculosis. One must get a good roentgenogram that shows bone definition, in order to examine these cases. One does not always get that; but in many of these cases one can see that a change is going on in the neck and in the epiphysis. Taking a series of roentgenograms, month by month, at times a thickening of the periosteum of the external layer can be seen where nature is trying to brace up a softened part of this neck; and unless these cases are treated by removing the weight-bearing, by ambulatory splints, the bearing of the weight on this soft bone will result either in telescoping of the bone and coxa vara of that kind, or in separation of the epiphyses from some trivial thing like stubbing the toe, as I have seen happen. I believe that they are not tuberculous cases, but are due to some other disturbance of nutrition. In some instances I have thought them syphilitic. In others they have appeared not to be so. In a number of cases the children are fat and have very slightly developed genitalia, and at times they have had more or less general malaise and ill health, following some disturbance such as measles.

Dr. Gwilym G. Davis, Philadelphia: An interesting case came under my observation recently. The patient was a boy 15 years old, who, over a year ago, was thrown from a sled and hurt his hip. He was under treatment for a short time and apparently recovered. Several months later he began to limp. After a time he would cease to limp, but later the limp would return. He was brought to me more than a year after his original injury and a roentgenogram showed a separation—or rather displacement—of the epiphysis. The case belonged to the coxa vara capitalis class referred to by Dr. Steindler. The epiphysis of the head was distinctly tilted downward, so that the hooked edge on the lower surface could be seen; but there was no change in the axis of the neck with relation to the axis of the shaft. Tuberculosis had been suspected, and the family history showed that taint in it. Now what is this boy suffering from? A dyscrasia like latent rickets, or solely as the result of an accident? If he is a healthy boy who has simply had an *epiphyseal separation, what explanation* can be given of the recurrent trouble? There is ¼ inch of shortening. I have seen cases of epiphyseal separation from fractures of the neck in children and they repair as quickly as any other fractures. This boy gets better, and then worse. Is it accounted for solely by the static condition? It may be; because he is extremely fat, heavy and big for his years. To such an extent is this so that it is suspected of being a case of infantilism. It may be that it is a case of lack of development, in which case one would put the boy, possibly, on pituitary extract. The whole question, to my mind, is an exceedingly obscure one and difficult of solution.

Dr. Emil S. Geist, Minneapolis: I believe that the subject of coxa vara will attract our attention a little more in future, since we have learned that some cases of coxa vara have been found in cases of congenital dislocation of the hip, in which reposition has been successful and the head centrally located. I have such a case to report, in which the operation of Lorenz was done on both sides eight years ago. The child is 14 years of age now, well developed and heavy. The heads of both femurs are in their sockets, but *there has supervened a marked degree of bilateral* coxa vara, giving the child a moderate "waddle." This will, perhaps, happen to any of us in some of these cases in which we have attained and maintained reposition.

Dr. John Ridlon, Chicago: In the last part of my paper, which was not read, I mentioned the condition referred to by Dr. Sayre and said that in the vast majority of the cases *the children are fat and have undeveloped genitalia.* It is the opinion of some internists that this condition of fatness and lack of sexual development is due to a want of normal balance between the thymus and the thyroid gland, and perhaps some of the other ductless glands are working irregularly. You may, however, find the feminine type of male in some cases without the excessive fat, and among these a good many of these cases of coxa vara that are not associated with fat. I formerly employed the long traction splint in the treatment of such cases, but I have now ceased entirely to use it; because in Case 1, in which there was a bilateral coxa vara, the deformity in the second hip developed a year or a year and a half after the first hip was well. In that case, I put on the ambulatory splint, a long traction splint, without traction being applied, to act as a peroneal traction. I put it on before there was any shortening or any evidence of coxa vara by the roentgenogram, and while wearing the splint he developed the shortening and a coxa vara that could be seen in the roentgenogram. The symptoms of lack of rotation and lack of abduction were present from the beginning. I am sure that the long traction splint will not prevent the development of coxa vara or help its cure, because I have seen patients recover without the long traction splint, without protection or any treatment at all, as quickly as when they have worn a protective splint. I am accustomed to stretch the leg with a machine, with abduction as far as is normal and to put the patients at once in the plaster spica and have them walk on the leg for some months until all evidence of sensitiveness has passed. I have had better results and a greater degree of lengthening in this way than with the traction splint. As to the relation of congenital dislocation of the hip to coxa vara, mentioned by Dr. Geist, I would say that I did not understand the case that he has in mind to be a case of coxa vara at all, any more than were those in the photographs shown by Dr. Steindler. Only one of those is coxa vara as I understand it. In replacing congenital dislocation, when the shortening is 1¼ to 2 inches and the muscles are very short, so that it takes two or three years to get the leg into normal rotation with a reasonable degree of motion, there is always an atrophy of the head of the bone from pressure due to the shortened muscles; just as in replacing a traumatic dislocation that has been out a long time. I replaced one that had been out three years, in a boy of 17; and two years afterward when he was going around on the leg, trying to get motion in it and to get it in the normal position, I found that there had been considerable pressure atrophy of the head of the femur. Therefore, change in and shortening of the head are, in my opinion, due to the pressure from shortened muscles, and not to congenital dislocation.

Dr. Arthur Steindler, Des Moines: The pictures that I exhibited were of cases of epiphyseal separation, so far as the roentgenogram gives information. I believe that not all epiphyseal separations show in the roentgenograms, and I should not rely on the picture entirely for the diagnosis; but two or three of my pictures do show an epiphyseal separation and a slipping of the epiphysis on the head, which has been described by German authors, producing a deviation in the axis of both the head and the neck of the femur. The patients were photographed a few weeks after the injury, as soon as the limp developed, and had not had time to develop coxa vara. I want to emphasize that the relationship of slight hip injuries to the possible development of coxa vara adolescentium has been established. All the cases that came under my care were traumatic, and a minor injury of that kind will bring about a separation of the epiphyses with the same degree of probability that a fall in the aged will produce fracture.

SEPARATE RENAL FUNCTION

OBSERVATIONS AS DETERMINED BY THE URETER CATHETER AND PHENOLSULPHONEPHTHALEIN *

GEORGE GILBERT SMITH, M.D.
BOSTON

Enough has been written about phenolsulphonephthalein to establish the value of this drug in the determination of renal function. It has seemed to me, however, that certain observations based on its employment in determining the function of the kidneys separately might be worth recording. The cases on which these observations were made were taken from private practice and from the records of the genito-urinary department of the Massachusetts General Hospital. The tests were done by me or by some other member of the genito-urinary staff.

The technic employed by all was essentially the same. When possible, both ureters were catheterized; if only one could be entered, the urine from the other was collected by a catheter in the bladder. After the urinary flow was established, 1 c.c. of solution containing 6 mg. of phenolsulphonephthalein was injected subcutaneously, intramuscularly or intravenously. The flow from the catheters was caught in test-tubes containing several cubic centimeters of 25 per cent. sodium hydroxid. The urine in most cases was collected from each side for fifteen minutes after the pink color first appeared from that side. These specimens were made strongly alkaline, diluted to 1,000 c.c. with water, and the percentage of dyestuff estimated by means of a series of graduated tubes of phenolsulphonephthalein solution, or by the Dubosc colorimeter. In most of the cases before the catheters were removed, the presence or absence of color in the bladder was ascertained by urethral catheterization.

In the earlier days of this test, the drug was injected subcutaneously or intramuscularly. We have noticed no important difference between the results obtained with one or the other of these methods.

We have the records of seven cases studied in this way and reported in such form as to make comparison possible. The results can be shown best in tabular form (Table 1).

In this series the time of appearance from the healthy kidney ranged from six to thirteen minutes, and corresponded fairly closely with the appearance time as determined in the test for total function. The percentage excreted by both kidneys together in the first fifteen minutes after the color appears should, judging from this series, amount to 6 or 8 per cent. when the total for one hour is about 40 per cent.

Following the intramuscular injection of phenolsulphonephthalein, the amount excreted in fifteen minutes is rather too small for careful estimation. Inasmuch as it is desirable to reduce the length of time required for the test, and since a much greater quantity of the dye is excreted in the same time after intravenous injection, this method has superseded the others for the past two years.

The results obtained are shown in Table 2.

The time of appearance from healthy kidneys after the intravenous injection of phenolsulphonephthalein ranges from one and one-half to six minutes, and in most of the cases is about three minutes. From the diseased kidney, the color may appear with very little delay, in spite of a function only one-quarter or one-sixth as great as that of the sound kidney. The percentage of phenolsulphonephthalein put out in fifteen minutes by the healthy kidney when its fellow is dis-

eased may range from 13 to 30 per cent. Case 11, in which there was proved to be no leakage about the catheters, put out 13 per cent. from the sound and 4 per cent. from the diseased side in fifteen minutes, yet the total function was 45 per cent. In nine cases out of the fourteen the function of the healthy kidney was between 20 and 30 per cent.; six of these put out 25 per cent. or better. To compare the work of these kidneys, whose mates were diseased, with pairs of healthy kidneys, we selected two outpatients who were under treatment for chronic urethritis and whose urines were normal, gave 6 mg. phenolsulphonephthalein intravenously and took the urine from the bladder at fifteen-minute intervals after the first appearance of color. The percentages were estimated by means of the Dubosc colorimeter.

Case T.—Appearance time, five minutes; first period, 60 c.c., 30 per cent. Second period, 50 c.c., 21 per cent. Third period, 80 c.c., 18 per cent.

Case H.—Appearance time, three minutes. First period, 110 c.c., 33 per cent. Second period, 120 c.c., 19 per cent. Third period, 100 c.c., 8 per cent.

Thus we see that in the first fifteen minutes a normal kidney should put out half of about 30, or 15 per cent. Only three of the sound kidneys in this series put out as little as that; most of them were already well along towards taking on the work which both kidneys should do.

As regards the output of the diseased kidney, we find in this series a fairly definite relation existing between the amount of dye excreted and the amount of kidney tissue. If there is little or no infection, this relation is very constant; if infection is an important feature, the function may be temporarily lowered by the interference of the exudate with the metabolic processes. The increase of function in Case 14 occurring after the removal of stones illustrates this. Case 13, with a good-sized stone in the pelvis, and no infection, showed a function of 25 per cent. Tuberculous kidneys in several instances have shown an unexpected decrease in function, considering the apparently large amount of healthy tissue in the gross specimens. In case 21, for example, with relative functions of 18 and 7 per cent., the diseased kidney showed nothing wrong except an abscess 2 cm. in diameter, and a sprinkling of miliary tubercles throughout the upper pole.

In the main, the phenolsulphonephthalein test in our hands has reported the value of each kidney with great faithfulness. Two cases in our series illustrate its accuracy unusually well, and will bear reporting in more detail.

Jan. 27, 1912, a woman of 29, Case 16, was cystoscoped. Clear urine and 10 per cent. dye were obtained from the left kidney; infected urine and 12 per cent. from right. The pelvic capacity of the right kidney was 40 c.c. and because of pain in that side the right kidney was explored by Dr. Hugh Cabot, the ureter freed and the kidney suspended. The pain was only partially relieved; the infection continued, and in July, 1913, the ureters were again catheterized. From the left kidney 30 per cent., from the right only 9 per cent., was obtained. It was obvious that the right kidney was losing ground, while the left was taking over its work. In September, 1913, the right kidney was removed and found to be one-third the size of a normal kidney and to consist chiefly of calices and pelvis.

The other case is that of a man of 37, who two years before had had a right-sided "nephritic abscess" opened and drained. Cystoscopy showed a slightly ragged, red orifice on the right. The left was normal. Both ureter catheters yielded clear, sterile urine, that from the right kidney containing very rare small granular casts. Intravenous phenolsulphonephthalein appeared in five minutes from the left, and in thirty minutes 15 per cent. was collected. Although the right catheter drained well, no color appeared during the thirty-five minutes consumed by the test. I was rather surprised at this and wondered whether the test was at fault. But a total intramuscular function showed an appearance time of 12 minutes with only 18 per cent. excreted in the ensuing hour. This confirmed the diagnosis of a useless kidney on the right and a left kidney which had not taken on the other kidney's burdens, and was in fact slightly below par for one of two normal kidneys.

The objection has been made that in carrying out this divided function test, the function of a kidney is liable to be depressed or in some way altered by the passage of the catheter up the ureter. An examination of the cases quoted above will show that in only two cases was the color obtained more quickly without ureteral catheterization than with it, and in these cases the difference was only one minute. The promptness with which healthy kidneys excrete the drug even though their ureters are catheterized upsets this objection. The amount of dye excreted, furthermore, as the tables show, corresponds fairly closely with the total hourly amount obtained from the bladder. Com-

pare the amount excreted by healthy kidneys with ureters catheterized with the standard set by the two intravenous, uncatheterized cases. The latter excreted 30 and 33 per cent., respectively; that is, 15 and 16.5 per cent. from each kidney; the percentage of these patients whose ureters were catheterized were 10, 25, 25, 13, 11, 25, 25, 19, 20, 28, 25, 25, 18. There is no inhibition of function here.

The point has been made, with much justice, that one cannot be certain of the accuracy of his results unless he has proved the absence of leakage about the ureter catheters by getting no color from the bladder while the catheters are still in place. With this position I heartily agree, but it has not been my experience to find leakage very frequently; if the ureter is not dilated, a No. 6 flute-tip catheter passed well into the renal pelvis and then withdrawn until it runs freely may be expected to carry off all the secretion of that kidney. The establishment of this point is of value in doing cases in which one ureter cannot be catheterized. In this series there are eight such cases; in four of them, no color appeared in the bladder at all, in one just a trace; in the others, the color did not appear from the bladder catheter until five, six and eight minutes after it appeared from the ureter.

The chief points drawn from this not very extensive study are these: After the intravenous injection of 6 mg. phenolsulphonephthalein, each kidney of a normal pair begins to excrete the dye in about three minutes, and in the next fifteen minutes puts out about 15 per cent. If a sound kidney which has a diseased fellow excretes 15 per cent., it is at least equal to one normal kidney; if more than that, it is already taking up the work of both. Such a kidney, according to our experience, may put out 30 per cent. in this period, or as much as two normal kidneys combined. Neither the time of appearance nor the amount excreted is materially influenced by the passage of ureter catheters, and the results of the test agree with great constancy with the actual pathologic condition in the kidney.

309 Marlboro Street.

ABSTRACT OF DISCUSSION

Dr. B. A. Thomas, Philadelphia: It is agreed that phenolsulphonephthalein is a useful functional kidney test. I do not believe, however, that, even in the capacity of quantitative determination, it supersedes in usefulness indigocarmin. In fact, I do not believe that it equals it, so far as relying on any single functional kidney test is concerned. We all agree that a metabolic quantitative study is the ideal procedure, but impracticable; on the other hand, that two or more tests are more valuable than one. I also believe that, irrespective of the quantitative determination, the use of indigocarmin qualitatively by the method of chromo-ureteroscopy, that is, its elimination from the ureteral orifice after intramuscular or preferably intravenous injection, has a slight advantage over phenolsulphonephthalein. In three cases I have found it absolutely impossible to catheterize the ureters even with a No. 5 catheter. There was undoubtedly a congenital stenosis of the ureteral orifices. Consequently, in such instances, any functional kidney test dependent on synchronous bilateral ureteral catheterization would prove useless. I therefore ask Dr. Smith or anyone using phthalein, if it be desirable to determine unilateral function, how is the test to be applied under such conditions? By chromo-ureteroscopy, on the other hand, it is easily possible to determine the function of the respective kidneys. Again, occasionally we will find, particularly in prostatic enlargement, the ureteral orifices so placed that it is impossible to catheterize even one ureter. Here indigocarmin once more enables us to determine the functional renal efficiency, unilateral as well as bilateral. Moreover, in quantitative determination dependent on ureteral catheterization one is not always sure of collecting the total amount of urine excreted. I have frequently seen, during the employment of indigocarmin, leakage around the catheter into the bladder. Ureteral lumina vary greatly in individuals. I believe the index of elimination, that is, the ratio of the quantitative determination of indigocarmin elimination for the third hour with the first hour, will give a more definite and reliable index of kidney stability and function than will the simple quantitative determination for the first two hours alone, because it takes into account the onset, the duration—the onset being delayed in disease, and the duration being prolonged—and also the ratio of the quantitative determination. I hope this method will be taken up by others and investigated and that it may prove to be a more definite and reliable indication of renal efficiency. I see no reason why it should not be applied to phthalein as well as indigo, although, in my experience, indigocarmin has been the more reliable.

Dr. M. H. Wyman, Baltimore: If one cannot catheterize either ureter in using phthalein, it seems to me it would be easy, although I have never tried it, to make the bladder solution alkaline. If the solution is alkaline, the first time a little spurt came into the bladder the time of appearance could be noted as easily as with indigocarmin. So I do not think that is any argument against phthalein.

Dr. William E. Stevens, San Francisco: There seems to be a tendency at present to limit ourselves to a single test. In my opinion this is a mistake. The indigocarmin certainly is of great value, especially when it is impossible to catheterize the ureters. The phthalein test is the most popular in this country, but in a series of about 112 experiments, using simultaneously the phthalein, phloridzin and quantitative urea tests, a marked parallelism was noted in all three. The urea test did not prove to be so valuable as the phthalein and phloridzin, but in our experiments the phloridzin, both as regards time of appearance and the quantitative estimation, were certainly as valuable as the phthalein.

Dr. George G. Smith, Boston: I have no animosity against indigocarmin. I use it quite frequently when I cannot catheterize the ureters. I think it is of great value under those conditions; but phthalein is a drug easy to handle, the amount excreted is rapid of determination, and what I have tried to show in my paper is that its use is accurate and reliable. Hence, I believe it is a perfectly safe drug to use. I do not see that the index which Dr. Thomas speaks of, the comparison of the first hour's output with the third, is of any value in ureteral catheterization and divided function, because in work in a clinic one cannot keep ureter catheters in place that long.

A Clean Bakery.—Those who are familiar with the insanitary conditions surrounding the handling and sale of foods in this city in the past realize that considerable improvement has taken place, particularly within recent years. The dealers and handlers of food have gradually come to realize the importance of cleaness and decency and, still better, are learning that it pays. Witness the following sign, advertising a bakery in Avenue B, the text being reproduced verbatim from the column conducted in the *Evening Sun* by Don Marquis:

"Our bakery is not in a basement where it can't come in fresh air, and what makes not to be clean.

"But our Bakery is on the grand floor windows with enough fresh air and sunshine and that means clean enough.

"We'll be very much pleased to show all apartments and machinery from our Bakery which is made after the Sanitary Rules from the Board of Health.

"We BAKE fresh every hour.

"We burn the COFFEE ourselves."—*Weekly Bull. Dept. Health*, New York City.

observed so often in tuberculosis of the bladder, rendering it impossible to use a retention catheter. It is marvelous to witness at times the relief afforded by ureteral catheterization and pelvic lavage. It is more particularly striking when a hydronephrosis exists.

The drugs most useful for this lavage are silver nitrate, aluminum acetate and mercuric oxycyanid, the first in a strength of from 1 : 20,000 to 1 : 10,000, which is quite as efficient as stronger solutions, and does not occasion disagreeable kidney colic; the aluminum acetate in a 2 per cent. solution, and the mercuric oxycyanid from 1 : 10,000 to 1 : 5,000. The lavage should be repeated once in five days. If the disease is confined to one kidney the ureteral catheter may lie in the kidney pelvis for several days.

Colon bacillus infection is quite a common disease in children. The majority of such cases will yield to an alkaline treatment and sweat baths. The hexamethylenamin preparations, when used with sodium benzoate, are also of benefit.

Vaccines are very useful in colon bacillus infections, more particularly autogenous vaccines. By their rational use it is quite possible to bring about the disappearance of pus and albumin from the urine and to banish the fever, but without the other measures they do not cause a disappearance of the microbes.

I would not care to treat serious cases of colon bacillus infection without these vaccines which have to be used with great caution. An overdose is often followed by a violent reaction with severe constitutional symptoms and aggravation of local conditions. I have one patient who easily takes a dose of 1,000 millions and I have another who at no time has been able to take a dose greater than 50 millions. Several times when I have tried to increase this dose the site of the injection has become inflamed, tense, excessively painful and to all appearances suppuration seemed about to take place, while chill, high fever, intense pain in the muscles of the back, headache, nausea and great mental depression followed.

The vaccines have appeared to do best when given at intervals of four days. If for any reason one is obliged to omit the treatment for a longer period than ten days, it is wise to return to the initial dose of from 10 to 25 millions.

The treatment of multiple abscesses occasioned by this infection; or of grave pyelitis or pyelonephritis that does not yield to general medical treatment plus drainage, or when the case is explosive and confined to one kidney, is the same as that for grave renal suppurations arising from other infective organisms.

PYELITIS GRAVIDARUM

Pyelitis gravidarum may be considered with coli infections. Pyelitis in pregnant women is a disease of great gravity. In 70 per cent. of the cases a colon bacillus is the infecting organism. It frequently attacks the kidney structures and destroys them and is often complicated by the formation of stones. With the pressure of the gravid uterus on the ureter occasioned by the drag of the uterus on the bladder there exists a certain atony of the muscles of the ureter, and the possibility of an ascending colon bacillus infection is greater under these circumstances than under any other that we know, for there are present all of the elements favorable to it: increased intravesical pressure, pathology of the ureteral mouths and the possibility of retrograde peristalsis in the presence of motile bacilli.

The attack is usually not sudden; a bacteriuria often exists for weeks or for months, and it is probable that in many instances a pyelitis in a mild form has existed from childhood, since colon bacillus infection of the kidney is very chronic and is often seen in female children. It is not possible always to differentiate between a pyelitis and a pyelonephritis, for casts and tubal epithelia may be present in the urine in both, from a previous nephritis existing independent of the pus infection.

The initial symptoms will sometimes resemble pneumonia, the pain in the side being close to the diaphragm causes interference with respiration and cough, but never expectoration. Persistent nausea and vomiting in the later months of gestation are very suspicious, especially when accompanied by intermittent pyuria. It is entirely different from the vomiting of the early months of pregnancy. Whenever in a gravid woman fever occurs, the cause for which is not exactly plain, and there is even very slight pain on pressure at the costovertebral angle on one side, it is well to suspect colon bacillus infection of the kidney pelvis as the trouble present, and search for it in the urine obtained by ureteral catheterization. In these cases there may or may not be a leukocytosis. If there is, it is never very high.

TREATMENT

An attention to the prodromes, ureteral catheterization and lavage will often abort an attack. Rest in bed, a milk diet and diuresis are necessary. If the child has a right lateral position, have the woman lie on the left side, and vice versa. Salol should be given in large doses. If these simple measures do not succeed, ureteral catheterization with lavage often will. The use of autogenous vaccines and, in persistent cases, a retained ureteral catheter should be tried. If the febrile symptoms do not then abate or the vomiting cease, choose between induced labor or a surgical operation, which should be nephrotomy or nephrectomy according to the condition of the affected kidney as indicated by the functional tests and by its appearance and feel at the time of operation. The prognosis is usually good for the mother as to life, but not good as to the production of a permanent cure without surgical interference. It is always bad for the child. In general, induction of premature labor is advisable, unless some special indications exist for not doing so, because the symptoms usually disappear very rapidly after the emptying of the uterus; if they do not, then nephrotomy or nephrectomy is to be resorted to. If nephrotomy is done the kidney should be sewed to the edge of the wound in the lumbar muscles and a thin, soft, pure rubber drain introduced into its pelvis and the kidney irrigated through and through by means of a ureteral catheter every two or three days with a solution of silver nitrate, mercuric oxycyanid or aluminum acetate.

A pyelitis due to any other infective organism should be treated in the same manner. In cases of multiple abscesses, pyonephrosis, it is better to do a nephrectomy primarily.

TUBERCULOSIS

Renal tuberculosis is a progressive infection, slow in its development, often remittent, probably incurable by medical means, due to the deposit of the bacillus of Koch within the tissues of the kidney by the blood-stream and perhaps sometimes by way of the lymph-channels.

It presents different types: First, the miliary form, distinguished by the deposit in the cortex of widely disseminated foci of granulation tissue containing tubercle bacilli; a complication of advanced pulmonary tuberculosis or a part of a general tuberculosis and having no diagnostic symptoms beyond the occasionally suspicious occurrence of renal hemorrhage or albuminuria and infiltration and irritation of the mucous membrane about the mouths of the ureters.

Second, a chronic parenchymatous nephritis with abundant albuminuria, scanty urine and dropsical effusions, without cardiac hypertrophy, and without increased arterial pressure. This occurs occasionally in the later stages of pulmonary tuberculosis and is of rapid development; the urine is irritating to the trigon, the bacillus cannot often be found, but guinea-pig inoculations are usually positive.

Third, it is asserted by some writers that there exists a tuberculous interstitial nephritis.

Fourth, and most important, is the form characterized by a slow infiltration of the parenchyma with minute foci of infection which tend to join with each other, forming circumscribed nodules or masses that soften or ulcerate and undergo caseous degeneration. Fortunately this process is at the beginning almost invariably unilateral, and occurs as a rule in persons who are not affected with active tuberculosis, but have lesions that appear to be cured, or present no evidence of tuberculosis. This is at the same time the most hopeful and the least hopeful of tuberculous changes in the kidney, and is the one usually meant when renal tuberculosis is spoken of.

SYMPTOMS

At its commencement there is no symptom or group of symptoms that is diagnostic. The first of all is vesical irritability, soon followed by the appearance of albumin in the urine and perhaps hematuria. The cystalgia is apt to be disregarded for a long time, the albumin to remain undiscovered until a free renal hemorrhage alarms the victim and sends him to the physician. Even then most generally the significance of the syndrome is not understood. Renal stone is a rare disease, renal tuberculosis a common one, yet the average consultant will search diligently for the calculus that is not there and forget all about the tuberculosis that is. The presence of pus in the urine is not long delayed and with it the agent of the process, the bacillus of Koch, appears.

It is important that the exact significance of this picture should be appreciated by every physician. Be suspicious of every case of prolonged vesical irritability the origin of which is not entirely clear, for therein a renal tuberculosis may be ambushed—a chronic infection, slow in its development, progressive, involving finally the entire urinary system, and mercilessly fatal—more important by reason of the fact that from its anatomic peculiarity early skilful surgical aid will effect a permanent cure in more than 50 per cent. of the cases.

MODE OF INFECTION

How does the bacillus invade the kidney? By the blood-stream in all but the rarest of instances; the process is exactly the same as that which takes place in the other hemic infections. When open tuberculosis, patent to the dullest clinician, active pulmonary lesions, joint or bone affections, or degenerations of the genital organs are present, the source of infection is so plain that no mistake can be made. Much more often a nidus of walled-in bacilli, the remnant of an infection of childhood, unheeded or unsuspected, exists in the lymph-nodes of the mediastinum or the neck; and under the depressing influence of trauma, acute inflammatory disease of neighboring parts, or impoverishment of blood following vigil, or overwork or overplay in vitiated air, softening of the caseated gland takes place, discharging sparse bacilli into the blood-stream attached to tiny fat droplets or tissue shreds, minute emboli of such low vitality that when arrested in the capillaries of an injured or diseased kidney they colonize slowly and without vigor, producing a form of renal tuberculosis which is from the onset essentially chronic, the clinical form which is the most important—that now under consideration—unilateral, nodular, caseating renal tuberculosis.

Why tuberculosis of any of the paired organs should almost invariably at the start be unilateral is difficult to explain, but it is a clinical condition of universal observation and this form of tuberculosis of the kidney is no exception to the rule; fully 85 per cent. of the cases are unilateral at the outset. It is this very anatomic peculiarity which renders them hopeful subjects for surgical therapeusis. If given time enough for development each one of these cases will eventually become bilateral infections and when they do it is too late to consider a cure by surgical interference. How long a time does this take? This varies with the virulence of the infection and the resistance of the patient. When it does occur are the bacilli derived from the original nest from which the first kidney was infected or is their source the diseased kidney itself? The researches of Israel on the rarity or banality of infection of the remaining kidney after nephrectomy for this disease give the answer of this question, for they show conclusively that the presence of a tuberculous kidney in the body of a person predisposed to tuberculosis is a greater danger to its healthy fellow than the presence of infective foci elsewhere.

It is interesting to watch these patients year after year when operation is refused. The great majority of them present an infection of the second kidney within three years and only about 20 per cent. of them live beyond the fifth year. In a few the disease appears for a long time to be really benign, the hemorrhages cease, the urine clears up, the vesical symptoms ameliorate and almost or entirely disappear, there is no inconvenience, the cystoscopic picture becomes almost normal, no tubercle bacilli can be found and even the guinea-pig test may be negative. This apparent cure is not accomplished at once but slowly, and to any agent that may have been administered or to any medical cult that may have been employed, a cure is credited. But, alas, these cures are but frauds; they do not exist; it is only the segregation of the infected focus that has taken place; firmly walled off from the sound kidney structures by inflammatory tissue which for the time being is sufficient barrier to their extension, and cut off from the urinary stream by the automatic ligation of the calix or calices of the diseased portions of the kidney, or perhaps the side-tracking of the entire kidney by the stenosis of its ureter, the bacilli sleep peacefully in their cheesy storehouse until constitutional disease or trauma or renewed activity once more liberates them. However long the interval of inactivity may be, the post-mortem table never shows these cases as cured. Once started, the disease is subject to many remissions but never disappears. The pity is that when we encounter a case there is no way to tell whether its progress will be slow or rapid; we only know that left to itself it in time will be fatal.

The kidney does not present on section the same appearance in all of these cases, but one is always impressed by the pathology of its incurability. Occasionally one finds calcified lesions but always with active nodules beside them; just as rare are perfect cicatrices indicating fibroid healing of a nodule, for beside or within them active foci can be found. The whole kidney, or one pole, becoming a cheesy cavern, often breaks down and is discharged through the ureter; but its walls, filled with purulent urine, are always covered with tuberculous granulations. Even the clear contents of the cysts found in excluded kidneys is fatal to guinea-pigs.

Of all the chronic infections to which the human body is subject, tuberculosis is the most kind. Judging from the experience of the operating room and the section room and the medical clinic, the enormous majority of those attacked by tuberculosis of the lungs, bones, lymph-glands, skin, etc., recover. Then why does not the kidney get well? Perhaps it does in the miliary forms and in tuberculous nephritis, but not in the caseous forms. There are two plausible reasons for this. The first is the universal tendency to destruction of the kidney tissue by the caseous degeneration, and the other the continued interference with the circulation of the organ and the retention in it of the urine loaded with tubercle bacilli, caused by the infection of the walls of the ureter and its obstruction by the inflammatory processes engendered thereby.

DIAGNOSIS

Recognition is easy to the instructed; very common, yet the medical profession in general never diagnoses more than one out of five of these cases until the kidney is practically destroyed. In addition to the existence of vesical irritability, pus, tubercle bacilli and perhaps blood will be found in the urine obtained by a sterile ureteral catheter from the pelvis of a suspected kidney. The patient should have a liberal quantity of water for at least two hours before the catheterization, and the urine should be collected for at least one hour. If acid-fast bacilli are not found or very few, or only spores are found after prolonged centrifugal sedimentation, the sediment should be injected into a guinea-pig, or the complement fixation test of Debré and Paraf, which consists of the demonstration of a tuberculous antigen in the urine, should be applied.

To an expert in cystoscopy the diagnosis may be surmised with an almost positive certainty from the presence of a peculiar injected appearance of the mucous membrane of the trigon which looks as if finely powdered paprika were blown with great force into it. There is also edema and not infrequently ulceration of the mucous membrane within and about the trigon and at the vesical neck. There is no distinct diagnostic appearance of the ureteral meatus, for this may be concealed in a mass of granulation tissue, deformed and constricted by ulceration, or lie open like a golf hole, or be only slightly puffed by the irritation of the bacterins. The chromogenetic functional tests aid only in determining the secretory capacity of the kidney without indicating the cause of its depressed function.

If the edema or ulceration of the trigon or stenosis of the ureter makes it impossible to catheterize the ureters, exploratory examination of each kidney should be made to determine which is the diseased one. We cannot be too strongly reminded of the fact that we must distrust the evidences of a tumor of the loin discovered by palpation when we are seeking the diseased kidney. The mass may be only a hypertrophied healthy kidney or it may be the sole functionating one also not free from disease. Each kidney should be brought from its bed on to the loin and its entire surface, and more particularly its pelvis and its ureter, viewed and palpated for pathologic changes. A diseased ureter will be thickened and adherent. The fatty capsule about a diseased kidney will be adherent in places to the true capsule, sometimes so intimately associated with it that it is impossible to separate them. In case of doubt it may be necessary to open both ureters some distance from the kidney and obtain a specimen of urine from them for microscopic examination before deciding which kidney is the diseased one.

Having made our diagnosis and ascertained the prognosis in the special case, what are we to recommend to our patient? There are but two ways of treating him, either by the general treatment for tuberculosis: climatic and hygienic measures combined with diet, drugs of the creosote class, and tuberculin; or we must subject him to surgical exclusion of the diseased kidney, nephrectomy. The combined work of many skilled urologic surgeons in all parts of the world during the past ten years has demonstrated that the only way to cure a kidney affected with unilateral nodular, caseous tuberculosis is nephrectomy.

It results in the immediate relief of 75 per cent. of the cases and in the permanent cure of 50 per cent. of them. If the surgeon is skilled in this class of operations, the immediate mortality should not exceed 6 per cent., and is for some as low as 1 per cent. The natural history of the disease shows that though remissions are many the progress is always relentless, eventually ending in death; but before the advent of the lethal day the diseased kidney invariably infects its fellow; and when the patient does not go out by reason of his renal tuberculosis he dies of tuberculosis of other organs. If the disease is far advanced and both kidneys are tuberculous, if one causes great distress and the other shows sufficient functional capacity to carry the burden of life, the less normal one should be removed. This operation is of course palliative only, for death usually takes place in the first year after operation.

Nephrotomy is not curative and should be resorted to only in distinctly suppurating cases, especially when the process has become perinephritic and when the general condition of the patient will be improved by temporary drainage awaiting a nephrectomy, to be done as soon as it is safe.

I find that it is not the explanation of the percentage of permanent cures resulting from the removal of the diseased kidney that moves many to submit to nephrectomy, but it is the atrocious and almost continual pain in the bladder that drives them to it in desperation, and usually the early stage has passed when this occurs. I very often have had the opposition of the medical adviser, for a large percentage of the older practitioners of medicine are skeptical about the existence of renal tuberculosis or are fearful of the results of operation, or believe that the patient can be cured by medical means.

"To prevent disappointment it is best to look on tuberculin as of assistance in the treatment of tuberculosis of the kidney and not as a specific remedy therefor." In forming an opinion of its value we must use as a base the reports of those who have had the patience to use it, over long periods of time, in numerous cases that have answered to the requirements of a perfect diagnosis: the direct demonstration of tubercle bacilli in an acid purulent urine received in a sterile container from a sterile ureteral catheter introduced into the pelvis of the kidney of a person afflicted with polyuria, dysuria or both; or the development in a guinea-pig inoculated with the sediment of this urine, of tuberculosis at the point of inoculation.

The evidence of experienced operators, who have frequently nephrectomized such patients with a low mortality both immediate and remote, yet who have had the courage thoroughly to test out the merits of tuberculin, is the best evidence of all, for they know and appreciate better than others the unreliable history of the disease and its unaccountable vagaries—how the individual develops a marked resistance to reinfection both from within and without, accounting for the slow progress of renal tuberculosis, its remissions of disturbing symptoms, and sometimes of apparent cure for months and for years, by the encapsulation and sealing up of the abscess cavity, thus introducing an element of doubt always into the origin of any favorable results following the use of tuberculin. Its use as a remedy in tuberculosis of the kidney can never be other than empirical. Many who have sung the praises of its curative powers have not always been very careful to make sure that their cases were tuberculosis of the kidney and were satisfied to report a cure when their patients increased in weight and the vesical symptoms decreased in intensity. There is no case on record that I have been able to find, that answers the full requirements of a cure of tuberculosis of the kidney by tuberculin; and yet there are many intelligent urologic surgeons who believe that it is possible if the disease is recognized early that it may be cured by hygienic and climatic measures if aided by tuberculin, and all agree that it is at least a useful placebo in bilateral renal tuberculosis, and in those cases in which one kidney having been removed the remaining one is attacked by the bacillus. Firmly convinced that in unilateral nodular caseous tuberculosis of the kidney, in the presence of a sound companion and without the existence of any other contraindication thereto, nephrectomy is the only remedy that promises a permanent cure, I have found it very difficult to convince the sick man and his friends of the benignancy of the operation in skilled hands and the necessity therefor, and so have been compelled to treat very many cases against my judgment as what was best, by tuberculin, duotal and hygienic measures. The clinical results in a few instances have been astonishing and in many fairly satisfactory, and were it not for the inexorable average history of unilateral tuberculosis of the kidney, did we not know that the walled-in abscess may contain living bacilli that hibernate for years only to be released by some mechanical insult or some lowered resistance giving rise to metastatic autoinfection again, I might well believe I had seen cures effected by tuberculin.

It is not a matter of much importance what particular preparation of tuberculin is used. The Belgians, and many of the French, use Deny's B. F. In Germany and America Koch's O. T. and N. T. and B. E. are in most general use.

The dose, however, is not a matter of indifference. It should be be small, always very small, at first. One that will equal from 1:1,000,000 to 1:100,000 mg. of O. T. is always sufficient to start with and it should be raised very gradually, avoiding the occasioning of a local or general reaction. The intervals of its administration should be four or five days. Used in this way it helps many and injures none.

ACUTE UNILATERAL HEMATOGENOUS INFECTIONS OF THE KIDNEY *

JOHN H. CUNNINGHAM, Jr., M.D.
BOSTON

At the meeting of the American Association of Genito-Urinary Surgeons in June, 1912, I reported a series of cases of acute unilateral hematogenous infection of the kidney, some treated by nephrectomy, others by decapsulation or drainage, and another group by non-surgical measures.

At this time it is my desire to relate the subsequent course of these patients and to refer to others which have come under my observation since that time. Tuberculosis, the most common of all hemic infection of the kidney, is not to be considered.

Suppuration within the kidney parenchyma, as is well known, results from infection by one or another of certain varieties of micro-organisms taking place usually in one or two ways, either as an ascending infective process from the lower urinary tract or brought to the kidney by the blood stream; yet rarely the kidney becomes acutely infected by adjacent septic foci or by penetrating wounds.

Ascending kidney infection is not the subject under consideration, and will not be considered, yet it must be stated that it is quite impossible in some instances of *Bacillus coli* infection of the kidney, to be certain that its origin is hemic and not ascending.

The acute renal infections of hematogenous origin are of two distinct classes: one induced by infective or toxemic conditions, for example, nearly all of the infections which give rise to general diseases such as diphtheria, scarlet fever, measles, small-pox, pneumonia, typhoid fever, etc. The disturbance within the kidney is due, in this class, to the action of toxic substances elaborated by the virus of the special disease which is in part eliminated through the kidneys. While the toxic substances of these acute general diseases conveyed to the kidney by the blood stream induce cellular necrosis, it is rare that suppuration occurs, and this type of hematogenous kidney disturbance remains medical rather than surgical.

It is the second, rather smaller, yet more serious, class of kidney infection of hematogenous origin, whereby the kidney is invaded by the micro-organisms themselves, resulting in acute inflammation and suppuration, that commands our attention from a surgical standpoint.

Acute suppurative nephritis of hematogenous origin is a condition resulting from the invasion of the kidney by certain micro-organisms, in particular by the pyogenic cocci and the colon bacillus. It is theoretically of a metastatic nature, and when encountered in both kidneys is usually consecutive to septic endocarditis or other septic affections elsewhere in the body. When it occurs in but one of the two kidneys the primary focus from which the organisms find their way to the kidney has seldom been determined; yet there are some instances in which acute tonsillitis, osteomyelitis and similar acute diseases of pyogenic origin may be correlated with an acute hemic infection of the kidney. Israel feels that he has been able to trace such renal infections to such simple infections as furuncles and paronychia.

---

* Read before the Section on Genito-Urinary Diseases at the Sixty-Fifth Annual Session of the American Medical Association, Atlantic City, N. J., June, 1914.

PATHOLOGY

The pathology of acute unilateral hematogenous infections of the kidney is quite different from the acute bilateral kidney infections. The latter are an expression of a general septicemia or pyemia in which the kidneys participate. The former, the acute unilateral kidney infections of hematogenous origin, are not a part of general pyemia, but find their origin in the lodging of a minute embolus carrying one or several organisms in the terminal vessels of the kidney. It is believed that the process may be started by a single micro-organism.

The condition starts not by multiple simultaneous points of infections throughout the kidney, as the lesions observed in the kidneys removed at operation might suggest, but as a single focus in the cortex of the organ. When the organisms settle in the minute capillary vessels of the glomerulus, an inflammatory reaction is set up around the glomerulus, and the surrounding tissue is infiltrated with the products of inflammation. From the primary focus of the infection other areas are secondarily involved by the infectious material gaining access to other tubules, to the lymph spaces and through the vessels in the connective tissue stroma. The infection thus is more or less rapidly spread through these channels to other parts of the organ.

The pathologic process originating as described above is of two distinct types: (1) *abscess formation,* and (2) *a diffuse inflammatory process without breaking down of tissue.*

In the former type of the disease, *abscess formation,* the kidney is found somewhat enlarged from congestion, and disseminated through its substance are small separate foci of suppuration or miliary abscesses surrounded by areas of congestion. In the early stages of the disease these minute abscesses are often observed in the cortex just beneath the capsule. From here other parts of the organ are secondarily involved, as just mentioned. If the process continues, these foci may enlarge, coalesce and form abscesses of larger size which may rupture the kidney capsule, and invade the perirenal fat, resulting in a perinephritic abscess. For the infection to complete this cycle, the resistance of the individual must be great and the virulence of the infecting organisms comparatively slight, as the systemic toxemia from this disease is rapid and death usually occurs before the process develops to this stage. The organisms producing this form of kidney inflammation are the pyogenic cocci, the *Staphylococcus pyogenes albus* and *aureus,* and the *Streptococcus pyogenes.*

The second type of the disease, *a diffuse inflammatory process spreading through the kidney substances, but not resulting in focal abscesses or solution of tissue,* has the same sequence of events in its pathology when of hematogenous origin. This type of the disease presents a pathologic condition more commonly the result of an ascending infection, but is encountered as a process of hematogenous origin and results not from an infection of the organ by the pyogenic cocci, as does the abscess type, but by the colon bacillus.

The difference in the severity of the process depends on the lesser virulence of the infecting organisms. The organ is found to be enlarged from congestion. There may be subcapsular areas of more or less acute reddening, and on section the organ is found presenting irregular, circumscribed, acutely reddened or pale yellowish areas involving the cortex and pyramids or involving nearly the whole organ, but without solution of tissue. In the early stage of the process these isolated areas are distinct and are seen as irregular, acutely reddened patches with the edges streaked downward into the pyramids. As the inflammatory process subsides, these areas lose the acute red color and are replaced by tissue of a paler character. In some instances the whole kidney may present an acutely reddened surface, owing to the acute process involving the whole organ. This form of the disease undergoes resolution without focal degeneration of tissues, and when seen after the acute process has subsided, presents paler areas, dependent on the stage of the connective tissue repair process.

By studying the clinical course of these two forms of the disease, it becomes evident that the clinical signs differ in some respects, and each has a definite relation with these two different pathologic conditions. The subjective and objective signs which the patient presents should suggest the type of process at work in the affected kidney, and these two types of infection should be recognized on inspection of the diseased organ at the time of operation, for experience has shown that these different types of infection do not require the same form of treatment. While the kidney containing numerous focal abscesses requires nephrectomy, less radical measures suffice in the diffuse, non-suppurative form of infection.

From the *clinical aspect* of the subject the picture which *unilateral multiple abscess formation* produces is an acute disease which may or may not be ushered in by chill. There is a rapid rise of temperature to from 102 to 105 F., and an early acceleration of pulse rate usually to 120 or higher, occurring often within twenty-four hours following the onset. Sepsis or toxemia and a high leukocytosis develop rapidly. Pain on the side of the affected organ, abdominal tenderness, muscular rigidity and spasm are found on the affected side. Lumbar tenderness, rigidity and spasm are pathognomonic signs of the disease. The abdominal signs are similar to those occurring in acute affection of the appendix and gall-bladder, for which this disease of the kidney is often, if not usually, mistaken. Unfortunately, the urine in this disease does not excite suspicion of the true condition, as it is usually quite normal in its gross and microscopic appearance, and genearlly contains but little albumin and only a small amount of pus and blood-cells, because the abscesses find no avenue of escape through the collecting tubules, which are either plugged by the product of inflammation or compressed by the infiltrated tissue surrounding them.

When the infection is severe, the patient grows progressively and rapidly worse, the toxemia becomes profound, delirium sets in and there is a fatal termination within a few days unless the body is rid of the infected organ. Of this form of the disease I have observed five cases. The following cases illustrate this type of the disease:

Case 1.—Woman, aged 38, entered the gynecologic service of the Boston City Hospital under the care of Dr. Franklin Newell and Dr. Ernest Young, March 27, 1912. The past history was negative, with the exception that one year ago both tubes, ovaries and appendix were removed for acute inflammation. The present illness was characterized by severe pains in the right kidney region, chills, fever and vomiting beginning three days before entrance and gradually increasing in severity. The temperature at entrance was 103.4 and the pulse 120, leukocytosis 28,000. The general condition of the patient gave every evidence of good health prior to the onset of the present illness. The physical examination showed a flushed face, throat and lungs negative, anemic murmur in the heart. The abdomen was not distended, but showed marked tenderness in the right side, less so on the left. Exquisite tenderness in the right upper quadrant and in the right loin. There was rigidity and spasm of the right rectus and lumbar spasms. Vaginal examination was negative. The urine was turbid, 1.020, acid, slight trace of albumin, no sugar or bile. The sediment was small in amount and consisted of pus, an occasional blood corpuscle and epithelial cell. The patient's condition became progressively worse during the following two days, and on the third day after entrance (six days after onset of the trouble) was extremely bad. At this time I saw the patient in consultation with Dr. Young. Her appearance was that of profound sepsis, pulse 130 of poor quality, temperature 103. There was a rigidity of the right side of the abdomen, with marked tenderness over the right kidney in front and in back. The urine at this time was only turbid and contained little pus. The leukocytosis was 18,000. An operation was advised as the only chance for life, although the risk was considered great.

A lumbar incision was made, the perinephritic fat found infiltrated with cloudy serum but no pus. The kidney was exposed and delivered. It was twice normal size, congested, and over the surface were scattered many focal abscesses from 1 to 5 mm. in diameter. The pedicle was clamped and the kidney removed. No attempt was made to tie the pedicle on account of the poor condition of the patient, stimulation and salt solution being required during the operation. The clamp was left on the pedicle; the wound drained by a spiral tube with gauze and the wound partially closed.

Twenty-four hours after operation the patient's temperature dropped to 100 and the pulse to 110. The improvement in appearance and general condition was perceptible. The clamp was removed from the kidney pedicle on the sixth day. The patient made an uneventful recovery.

The pathologic report was acute inflammation of the kidney, with multiple miliary abscesses from which *Staphylococcus pyogenes* was recovered.

Two years after operation this patient is living and well.

Case 2.—Woman, aged 32, seen in consultation with Dr. Albert Griffiths and Dr. Nathaniel Thayer at the Swedish Hospital, Brooklyn, Sept. 27, 1907. Previous health had been excellent. For two days the patient had complained of pain in right kidney region. There had been a chill, rise of temperature to 103, and urine was cloudy, containing 0.25 per cent. albumin and considerable sediment, consisting of pus, normal and abnormal blood, but no casts. The pain became more severe, and her general condition failed rapidly. When seen by me the general condition was poor, temperature 103.5, pulse 108, and urine as mentioned above. There was tenderness over the whole right side of the abdomen, rigidity and spasm of the right rectus. There was exquisite lumbar tenderness with spasm. The kidney was approached through a lumbar incision, the perirenal fat found to be edematous and adherent to the kidney capsule in the central third of the organ. The kidney when freed and delivered was found to be about one-third larger than normal and much congested. In the middle quarter an area about 1½ inches in length, of irregular surface, slightly harder than normal was found. This area extended over the anterior and posterior surfaces of the kidney to within about ¾ inch of the renal pelvis. The kidney was split in the convex border and the area observed on the surface was found to involve the central quarter of the kidney down to the renal pelvis. This area, darker than the surrounding tissue, contained several small foci of purulent material from 1 to 4 mm. in diameter. The remainder of the kidney showed only congestion. A wedged-shaped piece including the central third of the kidney and passing about ½ inch outside the infected area was resected. The upper and lower remaining thirds of the kidney were then brought together by mattress sutures. The wound was united around a tube and gage drain. The temperature dropped to normal on the second day following operation, and the abnormal elements disappeared from the urine. The patient left the hospital fifteen days after the operation with a small, clean, granulating wound. The improvement in general condition was rapid.

The pathologic report showed acute inflammation with multiple abscess formation. Staphylococi were demonstrated in the section, but the organism was not isolated. Dr. Griffiths reports that the patient has continued in good health since the operation (Sept. 27, 1907), now six years and nine months.

Case 3.—Woman, aged 34, presented the following clinical history: About five months ago she had an illness characterized by fever, pain in right side of abdomen and back. It was considered appendicitis by the attending physician. Remained in bed two weeks, at which time the symptoms had disappeared. An indefinite pain remained in right kidney region, more noticeable after physical exertion. Three months ago had a similar acute attack.

Aug. 1, 1906, the patient was again taken acutely ill, and when seen by me had a temperature of 101.8, pulse 110, and a leukocytosis of 18,000. The urine was negative except for a slight trace of albumin and a few pus and blood cells. There was severe pain in the right hypochondrium and acute tenderness and rigidity over the right rectus and in the right costovertebral angle. The appendix region was negative. During the following two days the temperature rose to 104, pulse to 120 and white count to 22,000. The urine remained the same. The pain, tenderness and rigidity became more marked and the patient began to look toxic. The diagnosis of acute inflammation of the kidney was made. The kidney was approached through a lumbar incision, the perirenal fat found edematous and the kidney about one-third larger than normal. Beneath the capsule were many small miliary abscesses. The pedicle was clamped and the kidney removed. The pedicle was tied and the wound closed with drainage. Within two days the temperature and pulse had fallen to normal and the general condition of the patient was much improved. The pathologic report was acute inflammation of the kidney with abscess formation with areas of scar tissue.

This case is of special interest because of the presence in the kidney of areas of scar tissue which may be correlated with the previous attack of illness with renal symptoms, as related in the history, and suggests that resolution of an infection of this type may take place.

Case 4.—Woman, aged 38, had had excellent health. Four days ago she was taken suddenly with severe pain in the right upper quadrant of the abdomen, accompanied by vomiting. She felt feverish and had several chills. When seen by me, Nov. 15, 1908, the temperature was 102.4, pulse 108, white count 17,200. In the costovertebral angle exquisite tenderness and marked muscular rigidity. In the right hypochondrium there was marked tenderness and rigidity, suggesting gall-bladder disease. Urine of high color, no bile, 1.014, acid, with a trace of albumin. The sediment was small in amount and contained many leukocytes, rare normal and abnormal blood-cells, hyaline and brown casts, occasionally fatty renal cells, and a few squamous epithelial cells. The patient remained in this condition without much change for four days, when it became evident that the toxemia was becoming pronounced, and the signs in the costovertebral region accentuated. The kidney was approached through the lumbar region, the perirenal fat found edematous, the kidney somewhat enlarged, and beneath the capsule could be seen many discrete abscesses about 2 to 4 mm. in diameter. A nephrectomy was performed, the pedicle tied, the wound drained; the temperature and pulse fell to normal on the third day; the abnormal elements disappeared from the urine except for the presence of epithelial cells. The pathologic report was acute inflammation of the kidney with abscess formation.

The patient was last seen in 1910 (four years after operation). At that time she was well, had gained in weight and considered her general condition better than it had been for years.

Case 5.—Boy, aged 17. Past history negative except severe tonsillitis seven days ago. Abdominal symptoms suggesting the peritonitis sometimes associated with tonsillitis appeared three days before patient was seen by me (Sept. 10, 1911). At that time the patient was acutely ill; temperature 103, pulse 110. White count 22,000. The tonsils were still acutely inflamed. There was tenderness over the whole abdomen and spasm on the right side. There was tenderness in the costovertebral space on the right. Urine 1.024, high, a large trace of albumin; a small amount of sediment, consisting of blood, large and small round cells and a few pus cells and granular casts. While the patient had been severely ill with tonsillitis from the onset, the attending physician believed the patient to be much more toxic since the onset of the abdominal symptoms. The patient was in a critical condition and it was believed that the right kidney had become acutely infected.

The right kidney was exposed through the loin. The perirenal fat was edematous. The kidney was enlarged about one-third over normal, and scattered over its surface were numerous foci of suppuration from 2 to 5 mm. in diameter. The kidney pedicle was clamped and tied, and the kidney removed. The wound was closed with drainage.

The pathologic diagnosis was acute inflammation of the kidney with abscess formation. The *Staphylococcus albus* and the *Streptococcus pyogenes* were found.

There was considerable improvement in the patient's condition during the following twenty-four hours, but he remained critically ill for ten days, when the temperature then reached normal. At this time the tonsillitis had subsided and the patient made a slow but uneventful recovery. Two years and six months after operation the patient was in excellent condition.

The *clinical picture produced by a diffuse inflammatory process within the kidney without abscess formation* differs from that with abscess formation chiefly in the severity of the symptoms and is the type of the disease most usually due to *Bacillus coli* infection and most difficult to distinguish from an ascending infection. The onset may be sudden, as in the former type, with acceleration of the pulse rate; and a leukocytosis is always present, often high. A chill may accompany the onset. Pain in the loin on the affected side is an early symptom, sometimes indefinite but often severe, varying according to the severity of the process. Tenderness over the kidney in the costovertebral angle, with some muscular rigidity and abdominal tenderness and rigidity on the affected side, is a constant sign. The chief feature differentiating this form of the disease from that of abscess formation is the lesser degree of progressive toxemia and the presence of more abnormal elements in the urine. These patients, while acutely ill, do not have the very severe and rapidly progressive toxic course which characterizes the other form of the disease. The illness after the first few days following the onset remains more or less stationary and may continue not unlike a beginning typhoid fever. The pain, tenderness and muscle rigidity may become gradually more pronounced, and the temperature, pulse and leukocytosis elevated, or the different signs may gradually decline. Remissions in the acute symptoms occur, but indefinite pain on the affected side usually persists indefinitely, and recurrences of the acute symptoms are not uncommon. The following cases are illustrative of this type of the disease:

Case 6.—Woman, aged 24, gave a history of syphilis four years ago. Treated with mercury continuously for three years. Jan. 7, 1910, laparotomy was performed by another surgeon because of severe pain on the right side of the abdomen, associated with spasm and tenderness over the right rectus muscle. At this time the temperature was 102.5. A few small cysts of the right ovary and a normal appendix were removed. A thorough exploration of the remaining abdominal organs proved negative. Following operation the pain in the right side persisted, the temperature ranged between 101 and 104, and the pulse around 120. The white count was 14,000. This condition persisted for about one week, when the temperature returned to normal, the pulse to 100, and the tenderness became much less.

One week later the pain again became severe, the temperature rose to 102, and the right side of the abdomen and back became very tender. Examination showed marked tenderness and involuntary spasm over the right side of the abdomen and back. White count was 23,000. The patient remained in this condition for about one week, when symptoms gradually subsided. The urine at this time showed but a trace of albumin, a small amount of pus, single and in clumps. A few small round cells and granular casts.

Two weeks later another acute attack of pain on the right side. Temperature rose to 102, pulse to 120. The twenty-four hour amount of urine at this time was 550 c.c. The sediment showed more pus, many small, round epithelial cells and a few hyaline and granular casts. Roentgen-ray examination was negative.

I first saw the patient in this attack. At this time there was general abdominal tenderness and spasm more marked over the right side. There was exquisite tenderness and spasm in the right costovertebral space. The general condition was only fair. The patient looked septic. The diagnosis of acute inflammation of the kidney was entertained.

An anterior incision was made, the peritoneum opened, the abdomen explored and found to be negative. The anterior incision was closed. The kidney was then approached through the loin. The perirenal fat was found adherent to the kidney and a hard nodule about the size of a Concord grape situated in the perirenal fat was removed. The kidney was slightly larger than normal and showed many red areas beneath the capsule. On section of the organ, similar areas were found scattered through the kidney substance. Nephrectomy was performed, the pedicle tied and the wound drained.

Four days following the nephrectomy the patient developed a right lobar pneumonia which a few days later involved the left side, and death occurred eleven days after operation. The wound at this time had healed except for a small granulating area.

The pathologic report showed acute inflammation of the kidney, with several areas showing connective tissue repair. The *Bacillus coli* was recovered from the tissues.

Case 7.—Man, aged 31, seen in consultation with Dr. Richard Collins at the Waltham Hospital, Jan. 25, 1910, since childhood has had a chronic discharge from the right ear. About ten years ago he had a severe attack of pain in the right kidney region, the facts regarding which are indefinite. Five years ago he had a similar attack and passed a small amount of blood in urine. He was confined to the bed for a short time. Four years ago he had a similar attack associated with fever, and frequent urination, and passed small amounts of blood in the urine several times.

Five days ago, after a hearty dinner, patient had a severe attack of pain in right side, associated with a chill and vomiting. He was then admitted to the Waltham Hospital, acutely ill, with pain on right side, temperature 102, pulse 104.

Acute symptoms gradually subsided, but pain in the back persisted. Roentgen-ray examination was negative. He was seen by me, Feb. 25, 1910. The patient's condition was as noted above. A cystoscopy performed at this time showed the bladder urine to be slightly cloudy and containing shreds. This urine was 1.020 in specific gravity, acid, and the sediment showed considerable pus, small round and many squamous epithelial cells. There was considerable fresh blood. Trigon was normal. Both ureteral orifices were normal in size and character. About ¾ inch above the right ureteral orifice was seen a group of eight or ten acutely injected areas from which bleeding had taken place and on which were adherent blood-clots. These areas were a little larger than a pin, and resembled early tuberculosis of the bladder. The remainder of the bladder was normal. Both ureters were catheterized. The urine collected from the two was equal in amount. The examination of the urine from the left side showed little abnormal; from the right side considerable pus and normal blood-cells; a few caudate and small round cells. Guinea-pigs inoculated for tuberculosis did not develop the disease.

Jan. 29, 1910, an exploratory examination of the kidney was made on account of the persistent pain and cystoscopic findings. The kidney was exposed through the loin. The perirenal fat was but slightly adherent to the kidney. Kidney was delivered and found slightly larger than normal. Beneath the capsules were seen a few grayish-white, contracted areas and a few acutely red areas. There was nothing abnormal in the remainder of the kidney or kidney pelvis. The kidney was split in Brödel's line. There were two acutely reddened areas in the upper half of the kidney. Believing the persistent pain to be due to these contracted areas, the kidney was removed, the pedicle tied and the wound drained.

The temperature, which was 101.5 at the time of operation, dropped to normal within twenty-four hours. The wound healed by first intention.

The pathologic report was an acute, diffuse inflammation of the kidney, with healed areas. The colon bacillus and *Staphylococcus pyogenes aureus* were recovered from the tissues. When last heard of, about one year following operation, the patient was reported to be well.

Case 8.—Woman, aged 43, seen in consultation with Dr. H. W. Barker and Dr. A. W. Tucker of Lynn; thirteen years ago had a severe illness, characterized by pain in the right side of abdomen and back, fever, chills and cloudy urine. She was in bed for several weeks. Since that time she had several similar attacks which confined her to bed for from two weeks to three months. The different physicians who have cared for her have considered that in these attacks she was suffering from "peritonitis." Some advised operation, which the patient refused. Between these attacks there has been a constant pain, varying in severity, in the left kidney region. Several Roentgen examinations have shown nothing abnormal. Four years ago the patient had a small amount of blood in the urine during one of these attacks. This occurred again two years ago. It never lasted more than a few days.

Feb. 2, 1912, the patient was cystoscoped by Dr. H. W. Baker and a collargol injection and roentgenogram were made of the left kidney. The cystoscopy showed the bladder to be normal in all respects, both ureteral orifices were normal, and the catheters were passed to each kidney. The specimen of urine collected showed that from the right side to be normal, and that from the left to contain a few leukocytes, normal red cells, and caudate epithelial cells. The capacity of the renal pelvis was 14 c.c. The roentgenogram of the injected kidney pelvis showed it to be normal. No shadow appeared in the control plate.

Feb. 14, 1912, I again cystoscoped the patient, and found the condition as previously stated. An injection of 6 mg. of phenolsulphonephthalein showed the dye to appear on the right side in six minutes; left in nine minutes. The total amount recovered in two hours was: right 25 per cent., left 10 per cent. On account of the persistent pain an exploratory examination of the kidney was undertaken. Temperature at the time of operation was 102.2, pulse 100, leukocytosis 8,100. The operation was performed Feb. 16, 1912. An anterior incision was made. The peritoneal cavity was opened and explored. Nothing abnormal was found. The peritoneum was closed and stripped toward the median line, exposing the left kidney retroperitoneally. The kidney was but little larger than normal, and several grayish depressed areas were seen beneath the capsules. On section there were many pale grayish, sclerotic areas, some near the cortex, others in the pyramid. The remainder of the kidney was reddish yellow, and there were acute red streaks near the apices of the pyramids.

In view of the history these sclerotic areas were considered to be old resolved foci of acute inflammation. It was believed that the persistent pain following the acute attack was probably to be explained by these areas, and the kidney was therefore removed. The fat about the pedicle was adherent to the vessels, and as they could not be cleaned the pedicle was clamped and the wound closed about the clamp, which was removed on the fourth day. The patient made an uneventful recovery except for an infection which took place in the wound.

Pathologic report is as follows: The surface presents several opaque, grayish areas which are depressed and contracted. Some of these areas are surrounded by a small area of injection, irregular in outline. On section several similar but smaller opaque areas not surrounded by areas of injection are seen scattered throughout the kidney substance. Near the upper pole is seen an area 2 cm. in diameter, symmetrical and definite in outline, containing another area which is apparently a blood-clot. The capsule of the kidney strips easily, leaving a red surface in places. Cortex measures 6 mm., and glomeruli are distinct. Histologic diagnosis is acute, diffuse inflammation of the kidney, with healed areas.

Three months after operation the patient was in the best health which she had enjoyed for many years. She had gained 34 pounds in weight. Eight months after operation excellent health continues. Two years and four months after operation the patient is in excellent condition.

Case 9.—Woman, aged 48, seen in consultation with Dr. H. Baker, March 2, 1912, presents a history of having had repeated attacks of pain in the left kidney region, associated with fever, chills and vomiting. These attacks confined her to bed for periods of weeks many times during the past five years. Since the first attack there has been constant pain in the left kidney region and during the past year the patient has been unable to lie down in bed and has been obliged to sleep sitting up on pillows. March 1, 1912, the patient was cystoscoped by Dr. Baker. The bladder was found to be normal. Both kidneys were cauterized. The urine obtained from the right side was acutely red and showed fresh blood, with a few squamous and large round cells. The fresh blood was believed to have been caused by the catheter. The urine of the left side was slightly cloudy and showed a few pus cells, single and in clumps, many squamous, polygonal and large round cells, many clumped with fat drops adherent.

The patient was seen by me, March 4, 1912. She was a poorly nourished woman, weighing 110 pounds, and complained of severe pain in the left kidney region. There was tenderness in the left costovertebral angle. The temperature was 99.4 and the pulse 108. As a result of the consultation it was decided that an exploratory operation of the kidney should be made.

March 10, 1912, the kidney was approached through an anterior incision, the peritoneal cavity opened and explored. Nothing abnormal was found. The peritoneal wound was closed and stripped toward the median line, exposing the kidney. The perirenal fat was slightly adherent to the kidney. This was freed and the kidney delivered. The organ was of normal size and rather pale. It was split in Brödel's line. The cut surface showed the tissue everywhere to be paler and firmer than normal, and there were no focal changes in the kidney tissue and the structure of the kidney was normal, other than for its pale character. It was decided not to remove the organ. The capsule was stripped, the kidney fixed in position, and the wound entirely closed.

The patient made an uneventful recovery. The wound healed by first intention, and two months following operation there is but slight pain of the old character, which has continued to come only after unusual exertion. The urine still contains polygonal and large round cells with a small amount of fat. Six months after operation the old pain had entirely disappeared and the urine contained but a few squamous epithelial cells.

It is believed that the pathologic process present in this kidney was a connective tissue repair of a diffuse inflammation involving the whole kidney. The kidney was left in this patient as more or less of an experiment.

This patient has had much relief, yet there is pain of varying degree in the region of the affected kidney, most distressing when fatigued, or when the urine becomes much concentrated. The pain may be considered annoying rather than severe. The patient considers herself much benefited but not cured by the operation. The urine examined many times shows renal cells and occasional granular casts; a small but variable number of leukocytes and sometimes fat globules. Her present symptoms do not warrant nephrectomy.

Case 10.—Woman, aged 55, was operated on twelve years ago for carcinoma of the breast. Eleven years ago she had an attack of lobar pneumonia. She was admitted to the Long Island Hospital Feb. 19, 1914, complaining of pain in the pelvis with bloody discharge from vagina. Physical examination revealed the following defects: A diastolic murmur was heard at apex; not transmitted. Vaginal examination suggested carcinoma of the cervix, and a histologic examination of the tissue proved it to be carcinoma.

April 30, 1914, I performed an abdominal hysterectomy from which the patient made an uneventful recovery.

May 20, 1914, the patient's temperature rose to 102, white count 14,000. Urine showed the slightest possible trace of albumin, a few squamous large and small round cells and a few leukocytes. The patient continued to run a high temperature and pulse; became extremely sick and eight days after the onset when seen by me the urine had become cloudy with considerable pus. There was tenderness and spasm over the whole right side of the abdomen and the right kidney could be felt considerably enlarged and extremely tender in front and in the costovertebral angle. Temperature 102, pulse 120, respiration 30. The kidney was exposed through the loin; the perirenal fat was extremely edematous; the kidney was considerably enlarged and of a bluish tint. Organ incised; surface acutely reddened throughout, otherwise negative. A rubber drainage tube was placed into the kidney pelvis and the cut surface closed about it. The external wound was closed about the drainage tube. The *B. coli* was recovered from the kidney incision and from the urine. The temperature dropped to normal within thirty-six hours and the patient's condition now, two weeks after operation, is satisfactory in every way.

Case 11.—Boy, aged 19, referred by Dr. George Muttart, had negative past history, except that he had symptoms of acute appendicitis for three days. Appendectomy was performed by me July 23, 1912. Free cloudy fluid was found in the abdomen and pelvis, considerable in amount. Abdomen and pelvis were drained. Patient made an uneventful recovery; wound healed on eighteenth day; on twentieth day following operation, the patient had a rise of temperature to 102 associated with a chill. The temperature continued to range between 101 and 103 for five days without other subjective signs except that there was indefinite pain in the right kidney region.

On the sixth day after onset of these symptoms there was marked tenderness in the right costovertebral angle and rigidity of the right rectus muscle. The urine for the first time became slightly cloudy and contained a trace of albumin and some blood and pus. A cystoscopic examination showed the bladder to be normal. The urine from the left kidney was normal, that from the right slightly cloudy, containing pus, blood and the colon bacillus. The patient was becoming progressively sicker, temperature 103, pulse 110.

The right kidney was exposed through the loin. The perirenal fat was filled with a cloudy serum, the kidney much enlarged and congested and beneath the capsule were seen many irregular areas of acute congestion. The kidney was split and these areas were found to be scattered through the kidney substances. A drainage tube was passed through the kidney into its pelvis and the kidney closed about the tube by mattress sutures. The external wound was closed about the drainage tube. The patient's temperature dropped to normal on the third day and the abnormal elements gradually disappeared from the urine. The patient is well almost two years following the operation.

During the past ten years I have seen seven patients in whom all signs pointed to a diffuse acute unilateral inflammatory process of the kidney, and in whom the symptoms subsided without operation. In four of these cases the colon bacillus was isolated from the affected kidney by means of the ureter catheter. The only sign of the disease remaining in these cases has been an indefinite pain in the region of the affected organ. In but one of these patients is this constant and in the others it may be considered absent, or present only during periods of fatigue. The urine in all shows but little abnormal. This type is illustrated by the following case, which is typical of this group:

Case 12.—Woman, aged 23, seen in consultation with Dr. A. L. Stavely and Dr. F. R. Hagner at Washington, D. C. Jan. 14, 1914, for many months had some indefinite feeling of discomfort in the right side, especially after playing golf, but no importance had been attached to it. January 8 she was seized with a severe pain on the right side of the abdomen, a chill and fever. The suspicion of appendicitis was entertained. When seen by Dr. Stavely her temperature was 102 and there was marked tenderness over the right kidney region associated with mucle spasm. Further examination showed a small amount of pus in the urine, a leukocytosis of 30,000 and the colon bacillus was isolated in culture from the urine. The patient became progressively sicker, the temperature ranging between 100 and 103. A cystoscopic examination by Dr. Hagner showed a distinct reddening of the whole bladder mucosa. The urine from the right ureter showed numerous epithelial cells and a moderate number of pus cells; the urine from the left kidney was normal. The kidney was injected with argyrol as it was thought that the patient might have a pyelitis. The temperature the following day (four days after onset) reached 104. The leukocytosis was 21,000; the polymorphonuclear leukocytes were 84.5 per cent. The patient's general condition was much worse and although the physical side had changed but little, the patient had become progressively more septic and the intoxication became alarming. When seen by me, six days following the onset, the patient's temperature had dropped to normal and the urine contained a considerable amount of pus for the first time. Physical examination was negative except for tenderness over the kidney region, in front and in the back, there being tenderness still existing in the costovertebral angle. The treatment, which had consisted of forced fluids and large doses of hexamethylenamin, were continued. The patient gradually improved and had no remissions of symptoms. At the present time, five months following the illness, the patient is in her usual health, although there is some indefinite discomfort in the right kidney region during fatigue. The urine is negative.

CONCLUSION

In the first class, the single kidney with multiple miliary abscess formation from which malignant toxemia results, the organ must be sacrificed in order to save the patient's life. In the second case of this class, mentioned in this report, only the central quarter of the kidney was involved. While this infected area was completely removed by a resection of the middle third of the kidney, and the healthy upper and lower thirds united successfully and the outcome of the case was most favorable, this procedure must be considered hazardous and cannot be recommended. In the other four cases of this class, here recorded, nephrectomy was performed, and it is felt that in each instance it was the only means which could have saved the patient's life. All these patients are living to-day and are free from symptoms, considering themselves well.

While house surgeon at the Boston City Hospital, I observed two cases of this form of the disease: one in which Dr. Paul Thorndike did a nephrectomy followed by recovery, and one in which Dr. F. S. Watson did a nephrectomy with drainage followed by death from progressive toxemia.

The proper treatment in the second class, the type of diffuse acute, unilateral inflammation of the kidney, cannot be so clearly defined and must depend on the course of the disease in the individual case. As a broad rule, it is felt that palliation, forcing fluids and the employment of urinary antiseptics, fortifying the patient's strength by a nutritious diet and stimulating drugs, should be instituted at the outset, and operative interference should only be undertaken when the symptoms and physical signs give evidence of progression to the point of seriously lowering the general resistance by toxic absorption. The time to operate in this class of cases requires experience with the disease and judgment in regard to the patient's general condition. Some of these patients recover without operation, as noted by Brewer, Cobb and others, and in the seven cases mentioned in this report.

When an operation is undertaken in this class, nephrectomy is not the only procedure to be employed. Favorable results have been obtained by simple decapsulation,[1] by puncture of the infected areas with drainage[2] and by splitting the kidney, closing the kidney wound by suture and decapsulating the organ or decapsulation and drainage of the kidney pelvis as in cases of this class recorded in this report.

On the other hand, when the symptoms and signs are of a distressing nature and the affected kidney is found to be the seat of old as well as new inflammatory processes or when the acute process is extensive, as in some of the cases of this report, nephrectomy is the best procedure.

46 Gloucester Street.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. MAC GOWAN AND CUNNINGHAM

Dr. Hugh Cabot, Boston: The distinction between the hematogenous and the lymphatic types of infection is of importance, and I believe it cannot be made from symptoms. From the symptoms alone we are likely to regard as hematogenous cases which are, in fact, lymphatic. The distinction has been made clearer to me by Dr. Cunningham's paper, and it turns sharply on the condition of the urine. I believe that, in practically all the cases in which there is evidence of a previous infection in the urinary tract, the infection of the kidney is lymphatic in origin. Mallory's work has shown that many of these cases of acute kidney infection follow mild cases of chronic pyelitis which have been entirely overlooked. In going over my records of cases of acute kidney infections I have been surprised to find how many gave a history of pyelitis, even many years ago, and some of these acute kidney conditions have originated in a pyelitis of childhood and are lymphatic in origin. The symptoms in Dr. Cunningham's cases are entirely out of proportion to the condition of the urine, because the condition is practically a closed one. It has little or no access to the tubules, and the urine does not show the extent of the damage. On the other hand, in the lymphatic cases secondary to a process in the pelvis, the condition of the urine follows quite accurately the symptoms. The cases that show very little change in the urine with marked general symptoms are likely to prove hematogenous, while the cases that give few symptoms and marked changes in the urine are of the lymphatic type. I was pleased to hear Dr. Cunningham lay great stress, in the treatment of these cases, on the desirability of great caution in the practice of nephrectomy. Modern surgery has shown that amputation, whether of an extremity or of a kidney, is an admission of weakness. Many kidneys have been taken out for conditions which would have recovered with a damaged kidney, but one far better than none. That does not apply to tuberculosis, but I am dealing only with infections from other causes. We should retain these kidneys to the last moment, and resort to nephrectomy only when the patient will die without it. In a considerable number of cases I have operated with the belief that I should be obliged to do a nephrectomy, and instead, have done some minor procedure, generally nephrotomy and occasionally decapsulation, with good results, though always with a damaged kidney. I do not believe that the majority of those cases are hematogenous. It has long been impossible to explain the lesions. They occur, as a rule, not in the glomeruli, but at the base of the pyramids in one group, and close to the pelvis in the other.

Dr. B. C. Corbus, Chicago: The work of Debré and Paraf, to which Dr. MacGowan made reference in his paper, consists in reversing the Wassermann reaction. We all know the difficulty of making a diagnosis in renal tuberculosis, both by looking for the bacilli in the urine and by guinea-pig inoculation. An animal is sensitized to the tubercle bacillus by injections of tuberculin, so that this animal contains specific antibodies for the tubercle bacillus. This "tubercle amboceptor" is used as an index, and the patient's urine contains the antigen. In the Wassermann an antigen looks for an unknown antibody. In the work of Debré and Paraf an antibody looks for an unknown antigen. The technic is simple. I have been working at it for a year, but failed until I could get a good antibody. One cannot get it from a tuberculous patient because his serum often contains both the antigen and antibody. If an animal is sensitized by injecting it with bovine tubercle bacilli you can get this specific antibody, and it is no trick at all to hook this back to the antigen in the urine. I have tried it in a few cases, but they are limited on account of the lack of material; but I hope later to have the pleasure of presenting this technic more fully.

Dr. M. Krotoszyner, San Francisco: Regarding Dr. MacGowan's statement that the cystoscopic evidence in renal tuberculosis is invariably to be found at or around the ureteral opening of the affected side, I recall a case of a tuberculous kidney in a woman of 42, in whom the cystoscopic findings were entirely negative. On account of this and the persistent absence of tubercle bacilli in the urine sediment, the diagnosis of tuberculosis, which was strongly suspected, was abandoned and the kidney was exposed without the application of the guinea-pig test, which was, in all probability, the only clew to a correct preoperative diagnosis. Two foci of tuberculous caseation were afterward found in the removed kidney.

Dr. J. H. Cunningham, Jr., Boston: With regard to Dr. MacGowan's remarks on tuberculosis and the clear summarization of them by Dr. Cabot, there is much of interest. The fact that we have never as yet seen a healed tuberculous process in a kidney that can be proved to be such is of primary importance. The lymphatic infection of the kidney, spoken of by Dr. Cabot, is interesting and I believe our attitude with regard to the manner in which the tuberculous process is disseminated in the kidney should be somewhat changed. What seems to be neglected, in considering infections within the kidney, is the fact that the kidney is an organ which may disseminate disease through itself by the channels already existing. We may have a single focus develop in a kidney as a hemic or ascending infection, and from that single focus other parts of the organ may be infected by the kidney channels. The cases which form the basis of my paper are examples of this sequence of events. I believe we have too often considered multiple lesions in a kidney to be simultaneous in this organ when, in reality, there was a primary renal focus from which other parts of the organ had become infected through the lymphatics, blood-vessels or the spaces in the connective tissue stroma.

[2] Brewer: Tr. Am. Surg. Assn., 1908, xxvi.

Dr. Granville MacGowan, Los Angeles: In this connection I will report a recent most interesting case. A man of 50, with pyuria, had had repeated attacks of left-side renal colic and had passed, at different times, a number of small stones after such attacks. Their frequency and severity had invalided him. A roentgenogram showed two large stones in the left lower pole. I catheterized both ureters, and obtained a macroscopically clear urine, which contained only a little albumin and a few red blood-cells. The phthalein test for functional capacity of the left kidney was better than that of its fellow; they were both normal. The patient had a large tumor in the left flank. I could satisfactorily explain this only by surmising the existence of two ureters on the left side leading to a double kidney, and that I had overlooked one. Following an atrocious attack I cut down on this kidney and found a perinephritis which was like a wasp's nest or honeycomb. The fatty capsule of the kidney was adherent to everything about it and so intimately to the muscles along the spine and the descending colon that they had to be dissected directly from it. The kidney itself was a sound organ lying in the midst of this undrainable surrounding tissue. There was no stone; the shadows had been cast by two cavities filled with granulation tissue, pus and débris which lay in the lower part of this mass and communicated with the ureter. The agent of infection was the *Staphylococcus aureus.* The kidney was removed inside its capsule, and the multiple abscess cavities were dissected off the healthy tissue *en masse.* The side had been injured two years previously by a blow from the crank of the patient's automobile. After the operation he was nauseated for days, and there was much pus in the urine for four days. On the ninth day, after a chill with a rise of temperature to 105 F., followed by anuria, on examining the right flank I found a tumor which proved to be a displaced kidney, probably dislocated by the retching following the first operation, causing a kink in the ureter. The kidney was exposed, delivered and decapsulated after pylorectomy to relieve pressure. Underneath the capsule of that kidney were hundreds of small miliary abscesses. The kidney presented by Dr. Cunningham reminds me of it. There was no abscess large enough to cut into and drain. The urine, which at the time of the preliminary examination had been normal, had during that nine days become infected. After decapsulation the kidney was suspended and drained for three days through the pelvis. At that time the patient's urine was perfectly clear, it contained no tube casts and no microscopic evidence of pus. I do not know, however, what the outcome will be.

Compiling Hospital Morbidity Statistics.—Bolduan has suggested a plan for compiling hospital morbidity statistics in this country. The method is especially applicable to the hospitals of a large city, but might be used for the hospitals of an entire state and is capable of being made nation wide in scope. The essential feature of the plan is the filling out of "discharge certificates," analogous to ordinary death certificates, on the discharge of each patient from a hospital. These discharge certificates are then sent to a central filing bureau, preferably the health department, and there classified and analyzed.—John W. Trask, Supplement No. 12, Public Health Reports, April 3, 1914.

AUTOGENOUS VACCINES IN TREATMENT OF SCIATICA

FRED. C. ZAPFFE, M.D.
CHICAGO

A man, aged 32, commercial traveler, consulted me because of an attack of sciatica (left-sided) which had continued practically unabated in the severity of the pain for eight months. During this time the patient had been under the continuous care of a number of physicians, but without more than slight temporary relief. He was kept from his work during all of this time, and, incidentally, lost not only time, but 60 pounds in weight. He was treated medicinally; the spinal nerve roots were injected with alcohol; he was given gonococcus vaccine; placed in a plaster-of-Paris cast; Buck's extension was applied to the leg; the Paquelin cautery was applied to the skin from spine to heel over the entire course of the sciatic nerve.

From these procedures he received only temporary relief. When I first saw him he was hardly able to walk because of the pain, nor could he lie down with comfort. He was in constant misery.

The history shows that he had an attack of gonorrhea six weeks before the sciatica began, and that about ten days after his doctor told him he was cured of his gonorrhea, he felt the first pain in the nerve. The clinical picture thereafter was characteristic of sciatica. There was no question about the correctness of the diagnosis. There was no evidence of a gonococcus metastasis elsewhere in the body.

Examination failed to find any pathologic condition except pain on pressure over the left sacral foramina. The spine could be put through the full range of motion, even violent motion, bending and rotating, without causing pain. Hip-joint disease was eliminated. Examination of the prostate gave negative findings. The teeth and gums were examined carefully and thoroughly by the patient's dentist. In short, there was no physical evidence of the cause of the sciatica, and yet when I took the temperature reading it was 99.6 F. at 8 p. m.

The examination was continued systematically. A Wassermann test was made, with negative results. The tuberculin test was also negative. The chemical examination was likewise negative. Roentgenograms were made of the spine from top to bottom, and of both hips and the pelvis. Very careful examination failed to disclose any evidence of anomaly or disease.

A clue as to the possible nature of the trouble was obtained from the temperature record. The curve was very erratic, the temperature ranging between 98 and 99.8 F., without any relationship to the time of day. The two-hour record was kept for a week and on not one day was the temperature normal throughout the day. The tuberculin test did not influence the curve in any way.

A bacteriologic examination of the urine was now made, and staphylococci and a diphtheroid bacillus were found. A culture of these organisms was taken and a vaccine was made. It was a mixed autogenous vaccine.

The first injection (hypodermically) of vaccine consisted of 100,000 bacteria. It produced a typical reaction. The patient felt slight chilly sensations; the temperature rose to 100.2 F., and the pain in the leg was somewhat increased in severity. The reaction subsided in twenty-four hours. Four days later the second injection was given. It consisted of 250,000 bacteria. Again only a slight reaction was obtained. The third injection of 500,000 bacteria, given four days after the second, produced a very slight reaction, but the fourth injection of 1,000,000 caused a decided reaction, far more marked than the first. Three more injections of 1,000,000 each were given, the reaction being slight after the first, and absent after the last two injections.

During the vaccine treatment the patient was encouraged to be outdoors, except for the first twenty-four hours after each injection; to eat well; to take some carefully prescribed exercise, and to observe personal hygiene thoroughly. He was given no medicine except magnesium citrate. The pain in the leg rapidly eased up and after the fourth injection ceased entirely and has not returned since. Eight months have now elapsed since the treatment was stopped. The patient has regained his normal weight, feels well, and is able to do all his work in perfect comfort.

The vaccine treatment of sciatica has not received the attention it deserves. Little is said about it in text-books, and only gonococcus vaccine is mentioned. Greeley[1] cites one case treated successfully with a vaccine made from a throat coccus. He gave only three injections — 100 million, 200 million and 400 million, respectively, with a final precautionary dose of 800 million. This is the only citation of its kind which I have been able to find in the literature. If there are other reports, they have escaped me.

These cases open up a wide field for vaccine therapy, but in order to follow it out intelligently one must be versed in the whole subject of vaccine therapy. The cases must be selected carefully and the treatment must be given with good judgment.

All the phases of vaccine therapy have been discussed almost, one might say, *ad nauseum,* and yet the subject is but little understood; in fact, it is greatly misunderstood. That it has a definite place in therapy no one will deny, nor that it has its limitations, largely, however, growing out of lack of discrimination and error in judgment in the selection of suitable cases. The case, the dose, the reaction, the time of administration and the duration of the treatment must receive careful and *individual* attention. There is no rule of thumb. The mere fact that it is now generally recognized that there exist strains of bacteria and that these strains differ from one another emphasizes the necessity that only from an autogenous vaccine can one expect to receive any favorable results. Stock vaccines are a "hit or miss" proposition — more often "miss" than "hit."

The source of the infection, that is, the infection focus, must be determined, and usually can be found by patient, persistent search. It may be elusive, but it exists. And when found, a vaccine is easily obtained.

Cases not amenable to vaccine therapy will yield negative results; therefore, every other possible source of the sciatic pain should be investigated thoroughly before vaccine therapy is tried, and then the same principles which make for success in this form of treatment in general hold good here.

This case is reported solely to call attention to one source from which a sciatica may take its origin.

Clarifying Culture Mediums.—Filtering culture mediums containing agar-agar has always been more or less responsible for breaking the Second Commandment in all laboratories. The laboratory supplied with a heavy centrifuge equipped with an interchangeable head, fitted with large trunnion cups and carrying 250-c.c. or 500-c.c. tubes or bottles, will find in this machine the solution to the troublesome question of filtering agar. In our own practice we use 250-c.c. bottles. In the case of ordinary nutrient agar, we centrifuge the hot agar-agar solution before mixing with the beef juice to remove all suspended, insoluble foreign matter. After adding the beef juice and heating, the whole is again centrifuged for two or three minutes, which separates the coagulate completely, leaving a finished product that requires no further clarifying. Precipitates that form on subsequent sterilizations are quickly and completely removed in this way. Even with other mediums that readily pass through paper, considerable time is saved by the use of the centrifuge.—W. F. Thomson, M.D., City Bacteriologist, Beaumont, Texas.

New Instruments and Suggestions

A LATERAL PRESSURE SPLINT FOR FRACTURED NECK OF THE FEMUR

George Chandler, M.D., F.A.C.S., Kingston, N. Y.

The need of a simple method of applying an old principle in the treatment of fractured neck of the femur is the reason for presenting a splint which is particularly valuable for use in the outlying districts of small cities distant from big surgical centers.

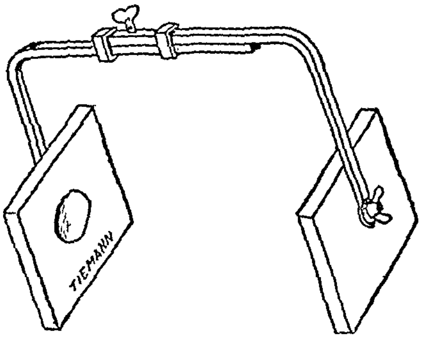
A surgeon practicing in a small town is frequently called into the country for a case of this kind and is confronted with the problem of giving his patient a satisfactory method of treatment without the appliances which a larger city affords.

In cities where assistants are at hand, large hospitals are convenient, and Roentgen-ray specialists can be secured, the abduction method maintained by a plaster-of-Paris splint, as advocated by Dr. Royal Whitman, is, of course, the ideal one.

A proper application of plaster of Paris, however, necessitates three or four assistants and an apparatus. This is obviously impossible in small communities.

Nor are the services of a trained nurse always available, on account of limited means, and it is conceded that, without proper watching, plaster of Paris is liable to produce pressure symptoms and other lesions in the aged, among whom this fracture more commonly occurs.

The method here described makes use of traction, abduction and lateral pressure, which are the principles of the plaster-of-Paris method, but embodied in a form that needs no skilled watching and can be applied by a surgeon unassisted. The method is as follows:



The author's lateral pressure splint for fractured neck of femur.

The patient is put to bed and a Buck's extension is applied as usual, the only difference being that the pulley at the foot of the bed is at the corner, and the patient's body is kept from the pulley side of the bed by sand-bags or bricks wrapped in flannel. By this means the leg is pulled obliquely away from the body, producing continuous abduction the same as in the Whitman method. After two or three days, when the muscles become sufficiently relaxed to overcome the shortening and to allow the fragments to be in apposition, the lateral pressure splint is applied.

The illustration shows it to be nothing more than a vise consisting of two boards connected by a sliding bar which is held in position by a thumb-screw. The boards are well padded and rest on either side of the hips grasping each trochanter, the adjustable bar being above and across the patient's pubes.

To adjust the splint, a hand is placed on either board and a gentle pressure exerted to press the boards against the trochanters. With the thumb screw loose, the sliding bars slip by each other and when the pressure is sufficient, a turning of the screw will maintain it and hold the splint solid.

The leg is at the same time held in a position which corrects the eversion of the foot, keeping it in its proper plane.

The cross-bar also serves to keep the bed-clothing from touching the patient and the splint gives him a sense of security. By reason of its firm grip, the use of the bed-pan is facilitated, as the patient can be rolled toward the uninjured hip without fear of displacement of the fragments.

Another advantage for the comfort of the patient is that the back can be easily bathed and rubbed, thus avoiding bedsores.

---

[1] Greeley: H.: New York State Jour. Med., April, 1914.

In impacted fracture the Buck's extension is not necessary, for obvious reasons, but the splint is of particular advantage in these cases, as it keeps the impaction from separating while healing is in progress.

During the past few years, I have used this splint successfully in fourteen cases, ages varying from 52 to 76 years, and have received reports from several other physicians who have had gratifying results from its use.

True, the diagnosis in these cases has been purely clinical and there have been no roentgenograms, but these cases had all the classical symptoms and were without doubt true fractures.

The patients, without exception, recovered and walked with remarkably little functional disturbance.

The simplicity, practicability and ease of adjustment of this splint make it an ideal method of treatment in communities where more elaborate appliances are not avilable.

AN APPARATUS TO ASSIST IN THE APPLICATION OF DRESSINGS ABOUT THE HIP*

H. W. Meyerding, M.D., Rochester, Minn.

In applying dressings, especially of plaster of Paris, in the region of the hip joint, a rest is needed which will add to the patient's comfort, allow sufficient working space, give a feeling of security during traction, permit easy removal and leave a well-fitting cast.

Patients not infrequently complain more of pain during and following the application of a cast than of the disease which required its application. Orthopedic surgeons find plaster a serviceable dressing because they have learned through experience to guard against the pitfalls attending its use. Sores due to pressure may be avoided by padding and smoothness of the area of contact. The sacrum is one of the most common sites of such sores, mainly the result of flat, ill-fitting appliances which leave irregular irritating areas supporting the weight of the body.

In order to insure perfect contact and avoid pressure-pain, the support should conform to the lumbosacral curve and allow as large a weight-bearing area as possible. Since a bone plate or graft may be loosened during the application of a cast, ease of application and removal are also important. An apparatus that will allow a certain amount of traction without slipping is also essential.

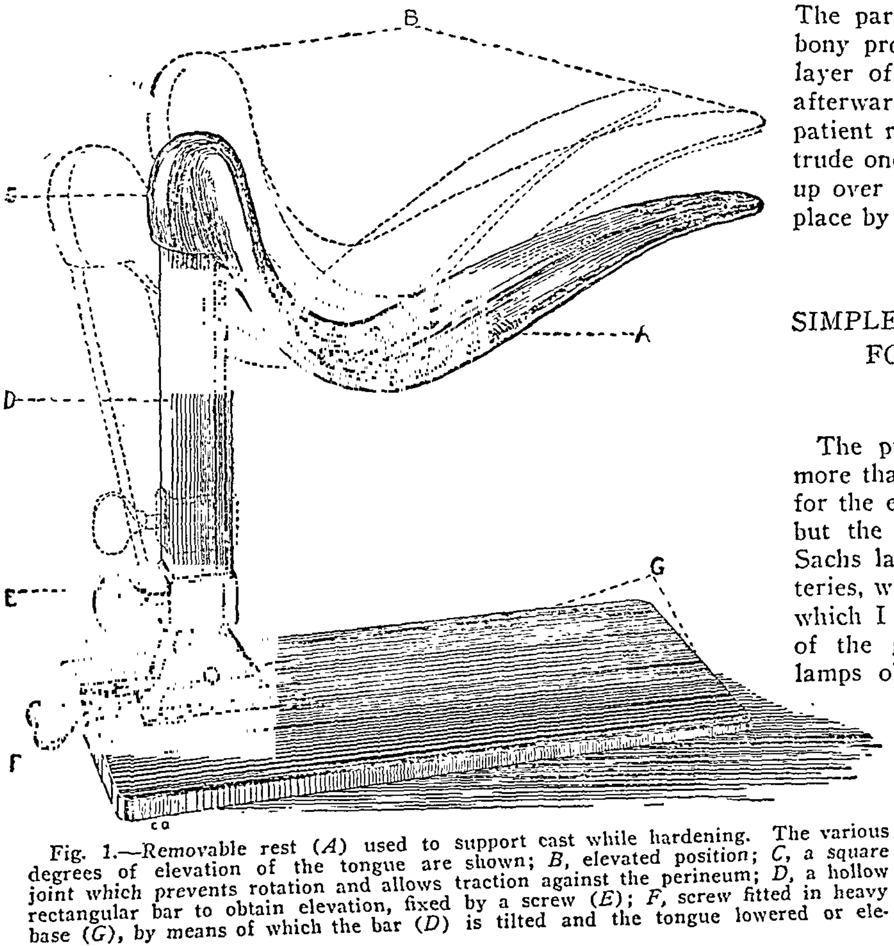


Fig. 1.—Removable rest (*A*) used to support cast while hardening. The various degrees of elevation of the tongue are shown; *B*, elevated position; *C*, a square joint which prevents rotation and allows traction against the perineum; *D*, a hollow rectangular bar to obtain elevation, fixed by a screw (*E*); *F*, screw fitted in heavy base (*G*), by means of which the bar (*D*) is tilted and the tongue lowered or elevated.

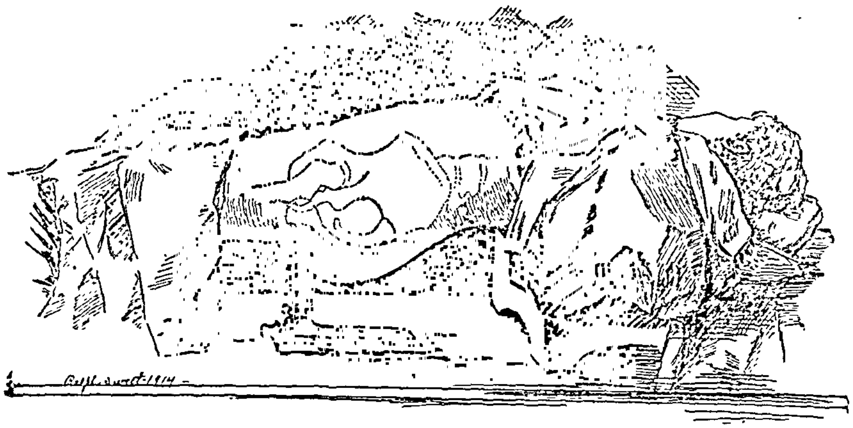

Fig. 2.—Sacral rest in position.

To meet these various requirements, casts of the lumbosacral region were taken of patients of varying ages in the prone position, and a support of average size was designed by me which has been used with satisfaction in the Mayo Clinic for the past three years. The apparatus is removable and can be left under the cast while hardening takes place. It may be lowered or elevated so as to meet varying degrees of tilting, as are found, for example, in ankylosis of the hip, and allows traction against the perineum (Fig. 1).

The patient is placed in position as shown in Figure 2. The parts to be covered are encased in stockinet, and the bony prominences are well padded with felt; then a single layer of flannel in the form of a bandage is applied, and afterward the plaster bandages. Trimming is done with the patient resting on the support, the flannel is allowed to protrude one-half inch beyond the plaster, the stockinet is drawn up over this and the rounded edges of the cast and held in place by a gluten bandage.

SIMPLE ADAPTATION OF POCKET FLASH-LIGHT FOR EAR AND EYE EXAMINATIONS

Ralph A. Fenton, M.D., Portland, Ore.

The principle of transillumination by a glass rod, used more than twenty years ago by Rochon-Duvigneaud of Paris for the eye, and later improved by Würdemann, is not new; but the instruments utilizing this principle (including the Sachs lamp) are all expensive and need special lamps, batteries, wiring, etc. No doubt others have hit on the expedient which I have used now for about four years: the addition of the glass rod to the smallest of the common flash-lamps obtainable.

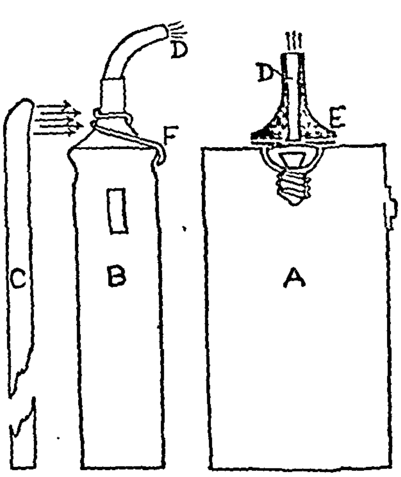
I take a small hard rubber syringe pipe, cut it off and drill out to fit tight over a piece of 3/16 inch glass stirring rod; cut the latter by nicking with a file to proper length, smooth the ends by melting in a gas or alcohol flame, and set firmly in place with collodion. The completed transilluminator is held in place over the end of the flash-lamp by a simple clip of spring nickeled wire, for example, a common paper-fastener straightened out.

For scleral or mastoid or frontal transillumination, or for throwing a small straight beam into the eye in looking for foreign bodies, testing pupillary reactions, etc., the simple straight tip is best. For use in the ear, the rod should be bent on a radius of about ½ inch, so that it forms rather more than a right angle, say 120 degrees. The upper end of the rod should now be roughly filed into a little hemisphere; melting this smooth gives us a lens tip. Now mount in a syringe pipe as before, and it will be found that the rays travel around with the rod, so that a splendid view of the tympanic membrane may be readily obtained. The advantage of this for bedside work, and the freedom from the necessity of carrying head mirror and hunting up a portable lamp, have made it almost indispensable to me.

---

* From the Mayo Clinic.

I also use a long rod acutely bent and then cut so as not to exceed its own diameter, and covered by thin rubber tubing, to carry a strong lateral beam into the nasopharynx. The view through the cocainized other nostril is then very clear. But this, and the fact that I have also adapted an old Marple electric ophthalmoscope to the same battery by using a glass rod of larger diameter to carry the light up to the point usually occupied by a miniature lamp of uncertain behavior, are not such generally applicable uses of this principle. I may say that on account of its portability and small size, as well as the ease of obtaining all the necessary repair parts, this home-made electric ophthalmoscope attracted much favorable comment in a number of clinics abroad and in the East last year.



Small hand battery, 2.7 volt flat top lamp; *A*, side view; *B*, end view; *C*, rod for nose and pharynx examination. *D*, glass rod. *E*, hard rubber syringe pipe. *F*, spring wire clip.

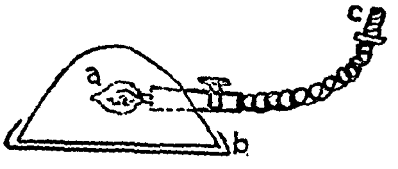
801 Stevens Building.

A CHEAP ELECTRIC HEATER

Edward von Adelung, M.D., Oakland, Cal.

The following device has been used as a substitute for a hot-water bag for over two years, and has proved effective, convenient and cheap.

The outfit consists of a 2-candle-power carbon filament lamp in an ordinary metal scoop-like reflector, with sufficient cord and a plug to connect with a convenient fixture. The reflector is converted into a metal box by a sheet of tin which is cut the proper size to close the open side of the reflector, leaving small ears to be bent over to hold the tin on. To prevent the metal from coming in contact with the skin, the box is slipped into a flannel or cotton bag with a drawstring. The arrangement is made clear by the sketch.



Electric heater; *a*, 2-candle-power lamp; *b*, tin cover, *c*, plug.

A 16-candle-power lamp burning twenty-four hours in this box will not light even paper; therefore with a 2-candle-power lamp there is no danger of fire. Still, such a small lamp yields all the heat that one can stand.

The ease with which one can use it without getting out of bed renders it especially convenient, and gives it an advantage over the rubber bag. It cannot leak. It is not heavy. When placed over cloths rung out of hot water, and the whole covered with flannel, an application is obtained superior to the ordinary poultice, and not requiring renewal.

Any electric house can put the parts together at a cost of not over two dollars. The cost of maintenance is practically nothing.

A CLINICAL METHOD FOR THE QUANTITATIVE ESTIMATION OF SUGAR IN SMALL AMOUNTS OF BLOOD*

Max Kahn, M.D., Ph.D., New York

There are no *clinical* methods for the quantitative estimation of sugar in the blood. The chemical methods that are in vogue are also not specific for glucose. Certain of these methods determine the *reducing* substances in the blood. By the polariscopic method we obtain the total quantity of optically active substances in the circulation. Those methods in which the glucose in the blood is extracted by certain solvents have no clinical value, because the amount of blood necessary for each test is too great.

The test here recommended determines the quantity of "reducing" substance in the blood. It is based on Bang's process. Control tests were made with various known solutions of glucose and accurate quantitative results were obtained. The process is very simple and should require not more than from ten to fifteen minutes for the whole analysis. Two solutions are prepared:

1. Copper Solution: Five hundred gm. of potassium carbonate, 400 gm. of potassium sulphocyanate and 100 gm. of potassium bicarbonate are dissolved in 1,200 c.c. of water, warming if necessary to from 50 to 60 C. (122 to 140 F.), and then cooling to room temperature. One hundred and fifty c.c. of an aqueous solution of 25 gm. crystallized copper sulphate are added. The solution is then made up with water to 2,000 c.c. It keeps indefinitely.

2. Hydroxylamin Solution: Two hundred gm. of potassium sulphocyanate are dissolved in 1,500 c.c. of water and a solution of 6.55 gm. of hydroxylamin sulphate in water added. This is made up with water to 2,000 c.c. This solution also keeps well in a dark-colored bottle. Equal volumes of these two solutions should exactly correspond to each other. The presence of proteins does *not* interfere with this test.

Into a weighing flask from 15 to 25 c.c. of the copper solution from a graduated buret are put, and the flask weighed together with the liquid on a chemical balance. Fifteen drops of the patient's blood (taken from an arm vein or from an ear lobe) are allowed to fall directly into the copper solution in the weighing flask. In experimenting with rabbits it is quite easy to insert a needle of rather large caliber into an ear vein, and thus draw off from 15 to 20 drops of blood, the needle acting like a cannula. The flask is now weighed a second time, and the exact weight of the amount of blood taken for analysis is thus determined.

The blood and the copper solution in the flask are brought to a boil and filtered through a Gooch filter with suction. The coagulum is washed until the washings are perfectly colorless, from 10 to 15 c.c. of water being sufficient for such washing. The washings are united with the filtrate and titrated with the hydroxylamin solution, which is added slowly from a graduate buret until all trace of blue or green disappears from the filtrate. Since 1 c.c. of the hydroxylamin solution exactly decolorizes 1 c.c. of the copper solution, the amount of copper present in excess is thus determined, and the difference between the original amount of copper and the excess represents the copper reduced by the "sugar" in the blood.

With this method a number of determinations of sugar in the blood were carried out. In most instances the results obtained by the foregoing process were higher than the figures given by previous observers. This may be presumably due to less manipulation because of the simplicity of the method.

---

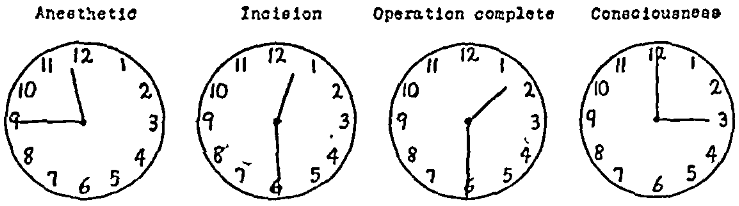
* From the Beth Israel Hospital Chemical Laboratory.

It was found that normal human blood contained from 0.14 to 0.19 per cent. of sugar. The blood of a diabetic patient who had a glycosuria of 2.7 per cent. contained 0.37 per cent. of sugar. Two nephritic patients had 0.21 per cent. (chronic interstitial nephritis) and 0.11 per cent. (acute parenchymatous nephritis) of sugar in the blood. In a very large number of analyses of the blood of rabbits, it was found that the normal sugar content varied between 0.11 and 0.18 per cent. (These experiments were carried out in the Government Laboratories at Washington, D. C.). Feeding sugar to rabbits raised the sugar content of the blood to 0.24 per cent. Subcutaneous administration of caffein (150 mg. per kilogram of body weight) induced marked hyperglycemia, the highest figure observed being 0.45 per cent. While zinc causes a marked glycosuria (by intravenous injection of the malate), it does not produce hyperglycemia; the sugar content in these cases seems to be normal or subnormal.

SUGGESTION OF CLOCK DIALS ON ANESTHESIA CHART

F. St. Clair Reilly, M.D., Havre, Mont.

As an addition to any good chart I think this will settle the question always asked the man at the head of the table, "How long have I been working?" It may also point an accusing finger at many surgeons. I believe it is better for the surgeon to wait five minutes than for the patient to breathe ether for forty-five before the first incision. These clock dials may be printed or put on the chart with a rubber stamp, and for the keeping of authentic records, only the stroke of a pencil is necessary.



Clock dials indicating unnecessarily prolonged anesthesia before beginning the operation.

A New Method for Hemostasis in Suprapubic Prostatectomy.—It requires no argument to prove that reliable and definite hemostasis is one of the principal requirements of the technic in suprapubic prostatectomy. Heretofore, procedures employed have been either by way of experiment, as the injection of serum, or temporary as digital compression, or an attempt at complete checking of the bleeding by tamponade of the prostatic site, which quite often led to renewed hemorrhage when the tampon was removed. The suturing of the prostatic cavity requires a considerable time and also may have as an accompaniment the retention of infectious secretions. It occurred to me to utilize the well-known hemostatic quality of fat for hemostasis in prostatectomy, using a free transplant of abdominal fat for a permanent tampon in the cavity resulting from the enucleation of the enlarged part of the prostate gland. The procedure is as follows: After completion of the enucleation the edges of the trigonal incision are seized with clamps and the cavity is temporarily packed with gauze, which may be advantageously dipped in serum. Now as much fat as its deemed necessary for the filling of the prostatic bed is dissected out of the abdominal wall, following either line of the skin incision, then the gauze packing is removed and the transplant is placed in the cavity resulting from the enucleation. The trigonal incision, now, with a few sutures inserted at the upper angle, is narrowed down to such a degree that any slipping out of the transplant is prevented. After this is done the bladder and abdominal wounds are attended to in the usual way. This procedure in nineteen cases so far was followed by such good results that I feel justified in recommending it to interested operators for further trial.—G. Kolischer, M.D., Chicago.

PRACTICAL PHARMACOLOGY *

(*Continued from page 149*)

II

DRUGS WHICH ACT ON THE CENTRAL NERVOUS SYSTEM

We may consider the drugs of these groups with reference to the dominant action, whether it be stimulation or depression, and with reference to the part of the nervous system on which they exert the most pronounced effect. The action of a drug is never limited to one part of the nervous system; though in a given case it may be exerted mainly on the brain or medulla. Few drugs produce stimulation without some subsequent depression, or depression without at least fleeting stimulation.

Drugs which act mainly on the central nervous system will be classified as follows:

A. Stimulants: 1. Drugs acting mainly on the spinal cord, but having *important actions on the* medulla (strychnin group).

2. Drugs acting mainly on the medulla, but having important actions on the brain or cord (atropin group).

3. Drugs acting mainly on the brain, but with important actions on the medulla or cord (caffein and theobromin).

B. Depressants: 4. Drugs which act on the brain first, then on the medulla (morphin group).

5. Drugs which act mainly on the heat centers (antipyretics and analgesics).

6. Drugs which depress first the great brain, then the cord and the medulla last (hydrocarbon narcotics). (Order of involvement of first importance.)

This classification (like others used in these articles) is only approximate, and no attempt will be made to adhere to it rigidly.

A. STIMULANTS: 1. ACTING MAINLY ON THE CORD—STRYCHNIN GROUP

There are several drugs which have an action on the spinal cord similar to that of strychnin. While this is of some importance as a side action, strychnin and nux vomica are virtually the only drugs which are used for increasing the reflex activity of the cord.

Thebain (an alkaloid occurring in opium) has an almost pure strychnin-like action on the cord, and caffein, morphin and codein possess the action to some extent, though they rarely exhibit it in man. Caffein and codein are seldom given in doses large enough to cause any increased reflex excitability. In morphin poisoning in man death results from paralysis of the respiratory and other centers before the action on the cord has time to develop. *In view of* the subsidiary importance of reflex stimulation in the action of these drugs, the present article deals entirely with strychnin.

Strychnin acts on the spinal cord of vertebrates in such a way that the reflexes are increased, the effect increasing with the size of the dose, so that with the largest therapeutic doses in man there is *distinct* twitching of the voluntary muscles, and with larger doses any slight stimulus, such as touching, induces a convulsive movement involving the closely related groups of muscles. If an excessive dose has been given, a stimulus which induces any reflex movement at all suffices to cause a convulsion involving all the voluntary muscles of the body. The intensity and duration of the convulsions increase with the size of the dose. The convulsion is followed by a period of depression varying from a few seconds to some minutes, and usually becoming longer with successive convulsions; but death may follow the first convulsion.

---

* This is the second of a series of articles on useful drugs—on practical pharmacology for the general practitioner. As soon as completed, these articles, elaborated by additional subjects, will be published in book form.

Strychnin convulsions are typical; there is at first a sudden contraction of the voluntary muscles, and if the dose has been very large this is immediately followed by tetanus with opisthotonos, the convulsion terminating with a few clonic jerks, followed by the pause during which the reflexes are actually depressed. If the first convulsion was brief, the depression may be followed almost immediately by a second convulsion if any stimulus is applied, or after an interval the length of which depends on various circumstances. The succeeding convulsions are almost exactly like the first in character, but they may be of shorter or longer duration.

ACTIONS OF STRYCHNIN ON THE MEDULLA

The actions of strychnin on the respiratory and vasomotor centers in the medulla probably differ only in degree from those on the cord, but it is difficult to determine the precise nature of this action on the medullary centers, and opinions differ as to the value of strychnin in conditions of circulatory depression.

When a normal animal is anesthetized and strychnin is injected into the circulation, no appreciable effect on the blood-pressure is produced until an amount is given equal to that which causes a distinct increase in the reflexes in a normal animal. Touching or pinching then causes a sudden rise of blood-pressure and a rapid return to normal. If a convulsive dose is injected, the rise in blood-pressure corresponds in duration to the convulsion. This rise of blood-pressure is wholly independent of any spasm of the voluntary muscles, for it occurs in exactly the same way in curarized (motionless) animals.

It is impossible to state whether or not therapeutic doses of strychnin affect the vasomotor centers so as to increase the blood-pressure when this is abnormally low, but it seems probable that in pathologic conditions with low blood-pressure, strychnin may render the vasomotor centers more susceptible to stimulation, and it is certain that it affects the circulation indirectly by increasing the tone of voluntary muscles through its action on the spinal cord in suitable cases.

The action of strychnin on the respiratory center is probably analogous to that on the cord, rendering it more responsive to stimuli, which normally play such an important rôle in the rate and depth of respiration, and under the influence of therapeutic doses of strychnin the carbon dioxid of the blood causes an increased respiratory movement, this being more pronounced when the respiratory center has been previously depressed by a narcotic.

With excessive (convulsive) doses of strychnin the respiratory center is first stimulated and later depressed. During the convulsions the respiration ceases, owing to the rigidity of the muscles of the chest; this causes an extraordinarily rapid increase in the carbon dioxid in the blood, which stimulates the respiratory center. Nevertheless, there is an interval, following the cessation of the convulsion and before the reinstatement of respiration, during which the center is evidently depressed, but this depression is much briefer than is the depression of the cord, as a rule, and the respiration begins shortly and is then deeper or more rapid than before the convulsion.

Following large doses the respiration fails to be reinstated after one of the convulsions, it may be the first, but usually after the second or third. Though opinions differ concerning the value of strychnin as a stimulant to the vasomotor centers, there is little doubt about its being an active stimulant for the respiratory center.

Strychnin stimulates the vagus center in the medulla, causing some slowing of the heart, but the rate of the heart depends on so many factors that this effect is not pronounced with therapeutic doses.

ACTIONS OF STRYCHNIN ON THE BRAIN

Strychnin increases the reflexes in the brain, especially those of the special senses, and vision, smell, hearing, touch and taste are rendered more acute. The effects on the eye and ear are utilized therapeutically. Strychnin sometimes exerts a marked psychic effect, causing a feeling of exaltation and relief from fatigue. This action is quite variable, and it is impossible to state when it may be expected.

ABSORPTION AND EXCRETION OF STRYCHNIN

Strychnin exerts a much greater action when administered intravenously than when administered in any other way, but it may be absorbed fairly rapidly from the gastro-intestinal tract and exert as great an effect after oral administration as after subcutaneous injection. The full effects of the oral dose are seen usually in about half an hour; the effects of poisonous intravenous doses are exhibited almost immediately. An extract of nux vomica, or a pill containing strychnin and some colloidal substance, is commonly employed when slow absorption is desired with prolonged action on the local nervous mechanism in the walls of the intestine.

Strychnin probably leaves the blood-stream very rapidly, and the larger part of a therapeutic dose is almost certainly eliminated from the body within a few hours, for fairly large doses may be administered several times daily for many days without causing toxic symptoms. Cushny states that elimination is not complete for a period varying from two to eight days. Strychnin appears in the urine soon after its absorption into the blood, and an amount equal to several times the normally fatal dose has been recovered from the urine of a dog in a period of five hours, during which large amounts of solution of sodium sulphate were injected intravenously in order to induce copious diuresis. (Unpublished experiments of R. A. Hatcher.)

TOXICOLOGY

Strychnin is among the most poisonous of the commonly used alkaloids, and as little as 0.03 gm. (½ grain) has proved fatal to a man. It is probable that the average fatal dose for a previously healthy adult is about 0.10 gm. (1½ grains). With appropriate treatment patients have survived much larger doses. One should never abandon hope of saving life until it is extinct, whatever the dose taken.

Death in strychnin poisoning usually results from respiratory paralysis, but a previously weakened heart may stop as the result of the sudden excessive rise in blood-pressure.

The method to be followed in the treatment of strychnin poisoning will depend on a number of factors, including the following: The total amount of the poison taken; the amount which remains unabsorbed (in case of its oral administration); the presence or absence of hyperexcitability or convulsions. Hence the following remarks are only intended by way of suggestion, and the treatment must always be adapted to the needs of the case in hand.

The physician will rarely be called on to treat strychnin poisoning after the administration of the drug in any way except by the mouth, because death usually follows so swiftly after the subcutaneous injection of a massive dose that no opportunity is afforded for effective interference.

So promptly does death usually follow the absorption of a fatal dose of strychnin into the circulation, that the mere fact that the patient is alive affords proof that at most but little more than the normally fatal dose has been absorbed, and when there is reason to suppose that any poison remains in the stomach, the chief efforts should be directed toward its removal or destruction.

If there is no increased reflex excitability, one should proceed to empty the stomach as quickly as possible. It may be washed with water to which strong tea[1] or half a pint or more of a 1 per cent. solution of potassium permanganate has been added, or with water alone if the tea or potassium permanganate is not readily available.

If the means for washing the stomach are lacking, an intramuscular injection of 6 mg. (1/10 grain) of apomorphin may be given at once, and strong tea or a pint of 0.5 per cent. solution of potassium permanganate may be swallowed by the patient. Should it become necessary to abolish vomiting, this may be done by inducing anesthesia with chloroform.

If hyperexcitability has been induced while there is reason to believe that the stomach still contains a notable amount of strychnin, the treatment is not so simple. It is imperative to remove or destroy any of the poison which remains in the stomach when it is practically certain that its absorption would prove fatal despite any treatment, but the washing of the stomach or emesis would be dangerous at a time when such measures are liable to cause convulsions. Emesis is then contra-indicated, and anesthesia must be induced before the stomach-tube is passed.

An especially difficult question arises when it is known that much more than the average fatal dose of strychnin has been swallowed, and when, owing to the length of time which has elapsed since it was taken, and the severity of the symptoms present, it seems probable that much of the poison has passed into the duodenum. In such a case the poison cannot be removed by gastric lavage, and it probably cannot be precipitated or destroyed by chemical agents, yet its complete absorption must almost inevitably prove fatal.

The procedure, however, in such cases must be much the same as in those in which some of the drug is supposed to remain in the stomach, and in addition, it is necessary to empty the bowel as quickly as possible, preferably by means of a copious saline cathartic.

The measures so far discussed are concerned with the prevention of the absorption of strychnin; apart from this are the questions of antagonizing its action after absorption and of hastening its elimination, both of which enter into consideration after absorption occurs, whatever the channel of administration.

Strychnin is eliminated by the kidneys, and whatever physiologic antidote is employed it should not interfere with diuresis, which should be promoted to the utmost. Hot tea or other hot liquids will induce diuresis, but the action is somewhat slow, and unnecessary loss of time should be avoided; hence a large amount of hot fluid should be introduced into the stomach, while as much should be introduced into the rectum and lower bowel as can be retained with comfort. In urgent cases it would seem to be justifiable to inject a quart or more of a sterile 2 per cent. solution of sodium sulphate into the veins, under suitable precautions, of course.

The value of ether in strychnin poisoning is shown by the fact that animals under its influence—they must be anesthetized completely—will survive more than twice the normally fatal dose of strychnin. Chloroform may be used to hasten the induction of anesthesia, but this should be continued with ether so long as may be necessary. Special stress is placed on the use of ether, for while hydrated chloral is commonly advised as an antidote to strychnin, pharmacologic experiments show that hypnotic doses of it are nearly, or quite, useless, and narcotic doses are dangerous in various ways. The dosage cannot be regulated so as to produce only the desired action; it is injurious to the heart; it lowers blood-pressure to the point that the respiratory center must suffer, while the elimination of the poison is seriously hindered.

Anesthesia may be maintained with ether without any of these disadvantages.

Artificial respiration should be employed when severe convulsions indicate that the respiratory center will suffer depression. One should not wait until actual respiratory failure occurs before instituting this measure. Unless the dose has been excessive, the convulsions can be controlled by this means. The inhalation of oxygen is an aid in hastening the destruction of strychnin. The treatment of strychnin poisoning may be summarized then as follows: removal of the drug from the stomach; precipitation by tannin; destruction by potassium permanganate; control of convulsions by ether; artificial respiration; elimination by copious diuresis, and avoidance of all stimuli, including touching the patient, noise and flashes of light. The chief reliance, if the patient is seen in time, must be placed in efforts to prevent the absorption of large amounts into the circulation.

THERAPEUTIC USES

Strychnin is probably not directly curative in any disease, but its capacity for increasing the activity of the reflex centers in the cord, medulla and brain suggest its employment in various conditions in which these centers are depressed, and its action on the vasomotor and respiratory centers indicates its use in various conditions attended with lowered blood-pressure and interference with respiration.

It is used in many forms of incomplete motor paralysis, but it should not be used when the paralysis results from a lesion in the cord, or in the presence of inflammation of the nerve-centers; it is especially contra-indicated in the inflammatory stage of infantile paralysis (anterior poliomyelitis). Opinions differ concerning its value after the paralysis has developed. In motor paralysis due to lesions in the brain, it is useful, in moderate doses, to maintain the tone of voluntary muscles through the increased reflexes.

---

[1] While the tannin of tea is useful as a precipitant of strychnin (Sollmann), it should be remembered that the beverage varies enormously in its tannin content. Some teas contain little tannin, and are practically useless for preparing an alkaloidal precipitant. While the physician is preparing to wash the stomach of the patient, he may have tea prepared as follows: Hot water is poured on the leaves and allowed to stand about one minute; this infusion is thrown away, because it contains caffein, which is synergistic with strychnin, but little of the tannin. Hot water is then poured on the leaves and allowed to stand about five minutes. This infusion contains most of the tannin and little caffein.

Respiratory stimulants are useful when the center is depressed by narcotics, including alcohol, chloroform, ether, hydrated chloral and morphin, and in diseases of the respiratory passages and the lungs, including bronchitis and pneumonia, when there is a tendency toward respiratory depression. Strychnin can be used, but it must be remembered that large doses of strychnin depress the respiratory center, after first stimulating it. Such large doses are therefore contra-indicated, especially in narcotic poisoning, in which the stimulant action of the strychnin might be entirely masked by the narcotic, and yet the depression due to strychnin would be added to that of the narcotic. Caffein would seem to deserve the preference as a respiratory stimulant in narcotic poisoning at least.

Strychnin is often used for increasing the blood-pressure, despite the fact that no essential increase follows the administration of non-toxic doses to normal animals. It is quite possible that its effects in pathologic conditions attended with abnormally low blood-pressure may be beneficial, and, indeed, Osborne states that it is the sheet-anchor when all of the vital centers are depressed in pneumonia.

It is often used in shock, but opinions vary concerning its value in that condition. The mechanism of shock is so little understood that it is impossible to state positively what the effects of strychnin are likely to be. Crile believes that it has no value in that condition, but that, on the contrary, it is decidedly harmful, actually increasing the danger. In cases in which respiratory depression is the primary cause of shock, it seems probable that strychnin may be of value, but we have no satisfactory evidence that therapeutic doses are capable of increasing the blood-pressure directly to any notable degree in shock.

Strychnin is often used with occasional benefit in disturbances of vision (amblyopia, amaurosis) when there is no anatomic change or only incipient optic atrophy, and in impairment of hearing of central origin. It is often used to improve the tone of the weakened sphincters (in enuresis), but when there is spasm of the vesical sphincter it is contra-indicated; atropin should be used instead.

The use of strychnin as a simple bitter for improving the appetite and digestion and as an addition to cathartics will be discussed in connection with other drugs belonging to those groups.

It is often used more or less empirically in many different conditions, in some of which it is certainly useful, but in others probably useless.

It is often recommended as a "cardiac tonic," but we have no evidence of its direct action on the heart. It may slow the heart through vagus stimulation at times; it may improve the circulation through its actions on the vasomotor and respiratory centers—for one cannot wholly separate the influence of the respiration and circulation—and thus through the circulatory changes it may improve the nutrition of the heart, much as it causes improvement in the voluntary muscles and other tissues of the body, when it improves the circulation by increasing the muscular activity.

MATERIA MEDICA

Nux Vomica, U. S. P., the seed of *Strychnos Nux-vomica,* an oriental tree, at present comes chiefly from India and Ceylon. The fruit, a berry, is of the size and appearance of an orange, and contains usually from two to five of the flat circular seeds embedded in a mucilaginous pulp. The seeds are hard and extremely tough.

The drug is probably the most widely used (and abused) article in our materia medica, and with its alkaloid, strychnin, it is prescribed more frequently even than opium and its alkaloids and derivatives.

Extractum Nucis Vomicae, U. S. P., a powdered extract which contains 5 per cent. of strychnin, is usually employed in the form of a pill or capsule, frequently combined with iron and quinin, as a bitter tonic.

It may be prescribed somewhat as follows:

		gm.	
℞	Extracti nucis vomicae.......	0|4	gr. vi
	Ferri reducti................	2|5	gr. xl

M. et fac pilulas xx.
One pill 3 or 4 times a day.

Or as follows:

		gm.	
℞	Extracti nucis vomicae......	0|4	gr. vi
	Quininae sulphatis..........	2|0	gr. xxx
	Ferri reducti................	2|0	gr. xxx

M. et fac capsulas xx.
One capsule to be given 3 times a day.

Tinctura Nucis Vomicae, U. S. P., is the more generally useful of the preparations of nux vomica, and is administered preferably diluted with water, or with water and syrup or fruit-juice at the time the dose is taken.

Strychnina, Strychninae Nitras and *Strychninae Sulphas,* U. S. P., are the three forms in which strychnin is official. They are colorless crystals or white powders, having an intensely bitter taste, which is perceptible in solutions containing 1 part of the alkaloid or its salt in 700,000 parts of water.

Strychnin and its salts may be administered in the form of pills, capsules or cachets, when the bitter taste is not desired. It is seldom administered by the rectum, but it is absorbed readily and may be given in the form of suppositories. It may be given hypodermically when for any reason the oral or rectal administration is contra-indicated, or when rapidity of action is essential; and in urgent cases it may be given intravenously in physiologic salt solution, of course, with the proper technic.

The salts are precipitated by the usual precipitants of alkaloidal salts, including alkalies, alkali carbonates, and by the bromids and iodids. Combinations of strychnin salts with precipitants in solution should be avoided, as the precipitate might escape detection and nearly the whole amount be taken in the last dose.

Dosage: The average single dose of strychnin, sulphate or nitrate, for oral administration is 0.001 gm. (1/60 grain), but the dose varies so widely that the statement of the average dose does not convey much information unless the purpose for which it is to be used is indicated. As little as 0.00065 gm. (1/100 grain) is often used as a bitter tonic, and as much as 0.010 gm. (1/6 grain) may be given daily for short periods. Much larger doses have been used, but there is no satisfactory evidence that they are necessary, and their use is attended with danger. The dose, whatever it may be, should be reduced or discontinued for a few days when the appearance of muscular twitching indicates that the therapeutic limits are reached.

The treatment of partial paralysis calls for the administration of doses of 0.003 gm. (1/20 grain) three or four times a day for ten days, with an interval of a week before continuing it. Halsey states that at least that amount must be given to overcome depression of the central nervous system, especially in infectious diseases.

Poisoning by hydrated chloral, alcohol, chloroform and other narcotics may be treated with an initial intramuscular injection of 0.004 gm. (1/16 grain); if this causes an improvement in the respiration the dose may be repeated in about two hours if necessary, but if the strychnin adds to the depression, or if there is no improvement with that dose, caffein should be used, and, as stated previously, caffein probably should be used from the beginning. Morphin interferes with the movements of the stomach, and since strychnin is probably not absorbed readily from the human stomach, it should not be administered orally in the treatment of morphin poisoning, but intramuscularly, to secure quick action, and later by the rectum if desired.

Strychnin salts are absorbed readily from the gastro-intestinal tract under normal conditions, and from the subcutaneous tissues, the dose being approximately the same whether it be given by mouth, rectum or subcutaneously. In emergencies its action may be elicited almost instantaneously after intravenous injection, but the dose by this method of administration is only about half the oral dose.

Some authors state that large doses of strychnin may lead to toxic symptoms through cumulation, because of the slow elimination, but there is no danger of serious poisoning to be feared when the daily dosage is limited to 0.010 gm. (1/6 grain), and the administration stopped on the appearance of increased reflexes.

XV

COUGHS

Before discussing the infections of grip and whooping-cough, it may not be out of place to refer to the varying kinds of cough. The trained nurse at the school, if not the teacher, should be able to note and describe the character of a child's cough to the medical inspector. Only by careful observation can the early stages of whooping-cough be suspected and discovered.

Coughing is an expiratory effort caused reflexly by some irritation. The muscles of the lower part of the chest are most engaged in the act of coughing; hence in severe, prolonged or frequent coughing muscle tire occurs in the lower part of the chest, both anteriorly and posteriorly. The abdominal muscles all take part in this expiratory effort, and the erector spinae muscles, the serratus, and the quadratus lumborum are all utilized in a strong expiratory cough. These muscle contractions compress in all directions the lower part of the chest, and the air in the bronchial tubes is forced upward, and if there is no obstruction is expelled through the glottis. If there is obstruction, or even partial obstruction, the upper portion of the lungs, especially the apices, become dilated, and temporarily, or in severe cases, permanently, emphysematous.

Cough can be caused by irritation of any of the mucous membranes of the air tract, by irritations of the nerves in the lung tissue, by irritations of the pharynx, by reflex irritation of the vomiting center, and by any irritation that can reach, through the pneumogastric nerve, the center in the medulla. From any of these reflex causes efferent impulses are transmitted, and the result is a cough. Irritation in the nose and ear may cause cough.

Pain and muscle tire from prolonged coughing, besides occurring in the lower part of the chest, occur in the sides, low down, perhaps in the region of the insertion of the diaphragm, and also in the back even down in the lumbar region. These strong contractions of the abdominal muscles during coughing also aid in temporarily diminishing the capacity of the thorax by pushing upward the abdominal organs. At the same time there is a considerable force exerted downward, which may tend to cause uterine displacements, hemorrhoids and even involuntary urination.

Before this forcible expiration or cough there is generally a deep, quick inspiration; then the glottis is partially closed and the air is propelled upward forcibly, causing friction which tends to expel anything on the walls of the mucous membrane of the bronchial tubes and trachea. Even in simple bronchitis, if there is much coughing, there will be found increased resonance in the apices of the lungs, as there is probably always a temporary emphysema.

Nasal irritations may produce cough as frequently as they cause asthma. Irritations of the nasopharynx and pharynx proper frequently cause coughing, which is very likely to be accompanied by retching and even vomiting. An elongated uvula may tickle the epiglottis and cause spasmodic, quick expiratory coughing. This cause, however, is rare compared with the frequency of cough caused by an enlarged lingual tonsil, whether the tonsil is hypertrophied, contains dilated blood-vessels, or is inflamed. Any disturbance of this gland or lymphoid tissue may cause a tickling in this region sufficient to produce a very irritating and disturbing dry cough, which comes on sometimes in paroxysms, until a certain amount of mucus is literally scraped off. The very intensity of the cough so irritates the part, like scratching a spot on the skin that itches, as to stop the tickling sensation for a time. Irritations of the larynx almost always cause cough. Hence no examination of a patient who coughs is complete without a throat and larynx observation.

The dry bark of spasmodic croup is very characteristic. The noise is low pitched, and is a bark. If it is husky there is mucus or membrane present.

The cough of bronchitis can be of all descriptions; it may be dry, may be non-productive, and may be moist and productive. Pain in such cough (the same is true of grip) is referred under the sternum, and is due largely to the vibrations of the air causing pain to the inflamed mucous membrane of the trachea and perhaps larger bronchi.

The cough of pneumonia is at first somewhat painful, and the pain is referred to the side, near the nipple. This cough may be at first dry, but is soon productive and generally should be encouraged.

The cough of pleurisy is non-productive and undesired, and is never loud. It causes pain referred to the side, and is repressed by the patient. There is nothing to expectorate, and it should be discouraged and stopped.

The cough in the first stage of tuberculosis is often dry and catchy; it is a hack. There is no great intensity to this cough, and no necessity for it, and it should be discouraged. As soon as there is much local bronchial catarrh the cough should, as it is then productive, not be discouraged, except at meals, and in the presence of others; that is, such patients should be taught when to cough.

The cough of asthma is a wheezing affair and accompanied by all sorts of rattlings; the same type occurs in a stuffy, asthmatic bronchitis. This cough is generally not harsh.

The coughs of different individuals vary. Some always cough with great intensity, and others easily and lightly. Older persons seem to raise mucus and pus from the bronchial tubes with difficulty. It takes a great many coughs to raise the sputum for expectoration. Young children generally cough easily, but generally swallow their sputum. Very weak patients will hardly expectorate at all. In such cases the foot of the bed may be raised at night; also when they cough, while in bed, they should turn onto the side or stomach in order to raise the sputum, or they should lean over in order to have gravity aid as much as possible the expulsion of the mucus, etc. The cough of pertussis occurs in showers or paroxysms, and at the height of the disease the glottis closes during inspiration and the air is sucked in through a more or less narrow slit, giving the characteristic "whoop."

Persons coughing very hard, as typically in whooping-cough, but also in emphysema and in the severe bronchitis of strong, sturdy men, will cause a great deal of cardiac disturbance by retarding the flow in the large vessels of the thorax, thus increasing the work of the heart, especially of the right side. Such coughing can force backward the blood in the large veins, thus congesting all the organs, notably the eyes, face and head, and whooping-cough can cause a cerebral hemorrhage or a hemorrhage into the eyes. These patients may not infrequently have nosebleed, and even vomit blood.

ACUTE BRONCHITIS

A child with an acute bronchitis, with expectoration, whether with or without fever, should generally be sent home; or if he is not acutely sick and continues to attend school, he certainly should be watched. There is no question that, whether bronchitis occurs in an adult or in a child, the patient will recover more quickly if he remains in bed for one or more days.

The prophylactic treatment is the same as for an acute coryza, and these treatments will more or less relieve the congestion in the bronchial tubes and promote expectoration, if the disease is not aborted. The cough is at first non-productive, but as soon as mucus begins to be plentifully expectorated the cough is productive, the tightness in the chest is relieved, and the patient feels better. One of the best promoters of a free mucus secretion is ipecac, and a few drops of the syrup of ipecac, given every hour, unless nausea is caused; or from 0.03 to 0.05 gm. (about ½ to 1 grain) of the powdered ipecac may be given every two hours. The ipecac should never be pushed to the point of causing uncomfortable nausea. The dose should, therefore, as suggested, be very small.

In the second stage of bronchitis there is no expectorant that seems to work so well as ammonium chlorid, and the dose should be about 0.25 gm. (4 grains) every two hours. The bad taste of this drug may be well covered up by giving it in a sour mixture, as the syrup of citric acid and water. If the cough is excessive and more than the secretion calls for, there is possibly no better method for its control than to give small doses of codein sulphate. This may be combined with the ammonium chlorid in a sour mixture, as:

		Gm. or c.c.	
℞	Codeinae sulphatis.........	0|20	gr. iv
	Ammonii chloridi..........	5|	ʒ iss
	Syrupi acidi citrici.........	25|	fl.℥ i
	Aquae..............q. s. ad	100|	fl.℥ iv

M. et Sig.: A teaspoonful, in water, every two or three hours.

This prescription is for an adult, but may be readily modified according to the age of the child. If the codein is not desired, it may be omitted. If it is desired to give the ammonium chlorid less frequently, the dose may be made larger. If a sweeter mixture is preferred, the syrup of tolu may be substituted for the syrup of citric acid; or both the syrup of citric acid and the water may be omitted and the syrup of wild cherry substituted.

If the larynx is inflamed, the inhalation of simple steam, or various other inhalants, may be of value, but a patient with laryngitis of any type should be under very careful observation by a physician.

If the expectoration becomes more profuse and seems not to stop readily, terpin hydrate seems to be of value. The dose is 0.30 gm. (5 grains) about four times a day. This may be given in tablet or in powder; solutions are unsatisfactory as it is very insoluble. If deemed advisable it may be combined with codein or heroin in small doses. There is, however, no real advantage in heroin over codein.

If the coughing persists longer than a week, the sputum should be examined to determine what germs are present. If it proves to be a simple bronchitis, but prolonged, sodium iodid in small doses may be of value, especially if the patient is at all asthmatic, or if it is in an older person. Fresh air, good food and iron are always of value in curing all kinds of bronchitis. If the patient is a child and the nutrition is poor, cod-liver oil is good treatment. A bronchitis that will not stop must be treated as a pre-tuberculous stage of tuberculosis, and the patient should receive climatic, or open air rest cure treatment.

It should be emphasized that a patient with bronchitis is not properly supervised unless the temperature is taken, and this more or less frequently. A patient with a fever should remain at home, if he wishes to avoid complications that readily occur from an acute bronchitis or grip. The district nurse or the medical inspector should always take the temperature of a coughing child. If a child has any fever, it should be sent home and the family physician summoned.

ASTHMA

As previously mentioned, a child in school that is found to be asthmatic should be carefully examined by the medical inspector and referred to the family physician, and if necessary, to a nose and throat specialist, to determine whether or not there is a reflex cause, and to have this cause removed if possible. The asthmatic habit once well acquired is difficult to cure.

COLUMBUS AND VESALIUS—THE AGE OF DISCOVERERS

Since the beginning of the new year, a series of celebrations of the four hundredth anniversary of the birth of Vesalius has taken place at various of the more important medical centers of the United States. There was to have been a magnificent memorial festival in Brussels, the birthplace of Vesalius, and an auxiliary celebration at Louvain, at whose university Vesalius obtained his preliminary and medical education. Owing to war conditions these celebrations were impossible, and it is interesting to realize that the great Flemish genius, to whom the world owes modern anatomy as it has developed for four centuries, had to look for the celebration of his quadricentenary to a country in the distant West discovered only about twenty-five years before his birth.

To Americans, perhaps the most interesting phase of Vesalius' life and career as a great founder in the most important of medical sciences is the fact that it should have occurred in such close relation to the discovery of America. His work represents a portion of the background of the intellectual life of Europe at the time of the discovery of this continent which must be known if the genuine significance of Columbus' great discovery is to be appreciated. Ordinarily, owing to rather limited knowledge of Columbus' environment and the difficulties which he encountered in securing assistance for his voyage, and the general skepticism with which his views as to the possibility of reaching land by sailing westward were met, it would seem as though there must have been little intelligence, slight diffusion of information, and an almost entire lack of incentive as regards human progress and development at that period.

Any such assumption, however, is quite contrary to the real state of affairs as regards culture and intellectual life during what may be called without too great demands on the historical imagination the century of Columbus, that is, the hundred years more or less from the birth of Columbus to the death of Vesalius. As a matter of fact, the number of men who did marvelously good work in painting, architecture, sculpture, and the arts and crafts at this time is wonderful. Columbus had in Italy three such supremely great contemporaries as Raphael, Leonardo da Vinci and Michelangelo. These are the greatest painters and sculptors since the time of the Greeks. They are much more, however. Raphael, besides being the greatest of painters, was one of the greatest of archeologic scholars of his time. Leonardo da Vinci once beat Michelangelo in sculpture, but thought of himself as a constructive engineer, and invented the wheelbarrow and the removable derrick, besides machines for sawing marble, lifting monoliths, filing saws and a number of others, and made basic discoveries in acoustics, botany and geology, as well as in anatomy and mechanics. Michelangelo was painter, sculptor, architect—nothing greater than St. Peter's has ever been built—and wrote sonnets that have only been equaled, probably not surpassed, by those of Dante and Shakespeare. All three of these men were alive in Vesalius' lifetime.

There were probably a score of artists in Italy in this period who would have been surpassing leaders in art at any other time. Such names as Titian, Botticelli, Fra Angelico, the Bellinis, the Vivarinis, Tintoretto, Veronese, Andrea del Sarto occur among the contemporaries of Columbus and Vesalius. Then, too, this was the great Renaissance period of scholarship, as well as the time when the most beautiful books ever printed were issued; it was the period of the learned women of the Renaissance, those scholarly "blue stockings" whom so many persons seem to forget when they talk of our period as the first in which women have ever been afforded the opportunity for the higher education. Besides, this period saw in every country in Europe a great development in music and the musical inventions, as well as in literature. Villon, for instance, and Charles of Orleans and the Pleiades and Rabelais did their writing at this time, and Montaigne was being educated for his life work.

It has been well said that whenever a period does any one thing well it always does well everything to which it seriously turns its attention. Following this rule, it is not surprising that there should have been a series of great scientists doing their work in what has been called the Columbus century. Copernicus revolutionized astronomy much more than even Vesalius did anatomy. Ambroise Paré, who has been called the Father of French surgery, wonderfully developed that department of medical sciences and practice. A series of botanists, practically all of them physicians, laid the foundation of botany broadly and deeply. The most important therapeutic discovery ever made, that of the use of mercury for the treatment of syphilitic conditions, received at this time its amplest development, with its indications and limitations. This is probably the most important period in the history of mathematics. Mechanics received a marvelous impetus from the great construction work undertaken by the architects of the time, and that magnificent series of contributions to the medical sciences in anatomy, physiology and clinical medicine was initiated. Such names as those of Eustachius, Fallopius, Columbus (Realdus), Verolius, Sylvius, Guinter of Andernach, Servetus, Fracastorius and many others occur at this time. Their books have now become precious treasures in medical bibliography. They were issued as a rule in magnificent printed editions not unworthy of Vesalius' own great textbook of anatomy, which has been declared probably the most beautiful medical book ever printed.

It is this background of the life of Vesalius and its relation to the discovery of America that should remain as a precious memory to the American medical profession, on whom the war has caused to devolve the duty of celebrating the four hundredth anniversary of the great Father of Modern Anatomy.

THE DELICACY OF ORGANIC REGULATION IN THE BODY

In the protest against the current tendency to seek the explanation of all physiologic processes in purely mechanical factors and to attempt the solution of the problems of living organisms on a physicochemical basis solely, the distinguished Oxford physiologist J. S. Haldane has cited some striking illustrations of the delicacy of organic regulation in the body.[1] We do not refer to these for the purpose of joining the author in his revolt against the hypothesis that life, as a whole, is a mechanical process, or to emphasize the difficulties into which the mechanistic conception falls when it deals with an organism such as that of man. The human body is a vast assemblage of the most intricate and delicately adjusted cell mechanisms, each being so constituted as to keep itself, as Haldane remarks, in working order year after year, and in exact coordination with the working of the millions of other cell mechanisms which make up the whole organism. The present comment is intended, rather, to point out some of the delicate and persistent responses that are encountered in the body — reactions that are all too often overlooked by the physician who centers his attention on some single organ or some localized function, and forgets the surprising interrelations between distant parts of the organism.

One of the most striking instances of this cooperative functioning is exemplified in the astounding fitness with which the kidneys, respiratory center, and other parts regulate the composition of the blood. Haldane reviews this topic as follows: The respiratory center is so extremely sensitive to any increase or diminution of the partial pressure of carbon dioxid in the blood that a diminution 0.2 per cent. of an atmosphere, or 1.5 mm. of mercury, will cause apnea, while a corresponding increase will double the breathing. The recent researches of Hasselbalch have afforded experimental evidence of what had already seemed very probable — that the stimulus to which the center responds is the difference in hydrogen ion concentration, or acidity, brought about by the very slight deficiency or excess of carbon dioxid. He has also investigated quantitatively the effects on the hydrogen ion concentration of the blood of varying the partial pressure of carbon dioxid. The hydrogen ion concentration of the blood during rest is extraordinarily constant, and remains so day by day and year by year. As the amount of acid and alkali passing into the blood from the food and other sources is constantly varying, it follows that the regulation of hydrogen ion concentration is mainly brought about by the kidneys. It has been known for long that the urine varies in acidity or alkalinity according to the diet; but Hasselbalch has measured the actual variations in hydrogen ion concentration. It appears that during ordinary resting conditions the variations in hydrogen ion concentration of the urine are about a hundred thousand times as great as those of the arterial blood. Thus the kidney epithelial cells react so delicately to variations in hydrogen ion concentration of the blood, that the very smallest variation in the direction of acidity or alkalinity excites them to excrete a liquid which is, relatively speaking, intensely acid or alkaline, the net result being that the normal hydrogen ion concentration of the blood remains practically constant.

The beauty of organic regulation is not confined to this field alone. We are reminded that we meet the same delicacy of adjustment in the regulation of such things as body temperature, blood volume, or heat production. So accurately does the body adjust its consumption of oxygen and of food material to its energy requirements that it can actually be used, as Rubner found, as a calorimeter; for it substitutes consumption of proteins, carbohydrates, and fats for one another in exact proportion to their energy values as determined with a calorimeter. In Liebig's time this delicate regulation was altogether unknown.

It may matter little whether such illustrations compel us to abandon attempts at a "simple" explanation in terms of chemistry and physics, and lead us to conclude with Haldane that such a conception of biologic processes breaks before the phenomena of life. We may prefer, with the mechanists, to await the further revelations of science before accepting any vitalistic or spiritualistic interpretations. Nevertheless, we can still agree with Haldane that "it is hard to realize that something which looks under the microscope like nothing more than a somewhat indefinite collection of gelatinous material can react, true as the finest mechanism of highly tempered steel, to the minutest change in its environment."

---

A NEW DEPARTURE IN MEDICAL LICENSURE

The unsatisfactory results of the conventional methods for drafting laws for the regulation of the practice of medicine have been generally admitted. In many states, the introduction of bills providing for separate boards and different standards for each new and fantastic sect or cult has become an expected feature of every session of the legislature. Yet the growth of knowledge regarding preventable diseases, and the increasing appreciation on the part of the public of the importance of state efforts for the conservation of life, are developing an appreciation of the importance of regulating equitably and permanently the licensing by the state of those who desire to treat the sick for compensation.

As an executive and as a member of both houses of the state legislature for many years, Hon. George H. Hodges, Governor of Kansas for the last two years, has had an extensive opportunity for consideration of this question. Realizing the unsatisfactory condition of the practice laws in most of the states, the governor appointed a commission to consider the entire question and to draw up and recommend for passage a bill providing a single standard for all persons desiring to treat the sick, regardless of the school of practice to which they might belong. On this commission were appointed Dr. J. A. Milligan of Garnett, formerly a member of the state senate; Dr. J. E. Sawtell of Kansas City; Prof. W. L. Burdick of Lawrence, dean of the law school of the state university; Hon. Fred D. Smith of Hutchinson, formerly speaker of the House of Representatives, and Mr. F. T. Ranson of Wichita, president of the Stock-Yards National Bank. This commission has drafted a bill providing for a preliminary examination of all persons desiring to practice medicine, surgery or any other form of healing art. The bill provides for a board of preliminary examination, made up of the chancellor of the state university, the president of the state agricultural college and the president of the state normal school, *ex officio,* who shall examine all persons desiring to treat the sick in any way. Any persons seeking a license from the state medical board, the board of osteopathy, the board of chiropractic or any other board must first satisfy the board of preliminary examination that he has had a four years' course in some reputable or established high school or its equivalent, and has spent at least four years of at least eight months each at some reputable professional school which includes in its course anatomy, physiology, pathology, surgery, obstetrics, chemistry, bacteriology, symptomatology, diagnosis, urinalysis, hygiene and sanitation. Suitable sections for the administration and enforcement of the act are included, together with sections amending the medical practice, osteopathic and chiropractic laws so as to make them uniform with the proposed bill.

Medical practice acts are primarily and solely for the good of the public. The report of this commission marks an epoch in medical legislation. It is the first distinct recognition of two important principles which must sooner or later dominate such legislation in all of our states. The first is the necessity and equity of a single standard for all persons, regardless of "schools," and by inference, the inequity of different standards for different schools. The second and equally important principle is that the examination and licensing of persons desiring to treat the sick for compensation is not a medical but an educational problem. The recognition of this fact in the designation of the three leading educational authorities of the state as the board of premliminary examination is a most important step in the development of better conditions in state regulation of the practice of medicine.

DYSPNEA IN CARDIORENAL DISEASE

Certain types of both cardiac and renal disease are attended with disturbances in respiration which occasion unpleasant manifestations. Sometimes the conditions of the heart and kidneys are believed to contribute jointly to the difficulty that may arise. The occurrence of Cheyne-Stokes breathing in uremia has been attributed to cardiac failure which is undoubtedly one of the common causes of such dyspnea; but the labored breathing at times attending renal disease may be independent of the heart in its origin. There is urgent need to-day of a clearer understanding of the immediate physiologic and pathologic conditions which underlie dyspnea, instead of the vague charges against the different organs which are more indirectly involved in the transaction.

The questions to be solved concern the nature or size of the stimulus to rapid respiration. The well-established view that the exciting stimulus to the respiratory center is the carbon dioxid content of the blood has been broadened to refer to the hydrogen ion concentration of the circulating fluid. The variations in the carbon dioxid content of the blood, and consequently of the alveolar air, are but the result of the attempt on the part of the organism to keep the hydrogen ion concentration of the blood at a constant value. The carbon dioxid in the blood rises as the amount of non-volatile acid falls, and the carbon dioxid falls as the production of other acids rises. Any tendency to the production of an acidosis in the body is immediately compensated for by an increase in respiration and a washing out of carbon dioxid. It seems probable that the kidney is the fundamental regulator of the reaction of the blood, but the lungs, acting more quickly in response to sudden calls, serve, as has lately been remarked, as "the more delicate balance-wheel of the regulatory mechanism."

Hasselbalch[1] has emphasized the fact that in addition to the acid stimulus, the excitability of the respiratory center must be taken into account in any consideration of the factors that govern the chemical regulation of respiration. Even with an unchanged composition of the blood in respect to non-volatile acids and carbon dioxid, the threshold of excitation of the center may be altered and change the respiratory function. According to Lindhard,[2] the excitability of the respiratory center varies inversely with the oxygen tension.

Blood, which directly bathes the respiratory center, urine, which represents the outcome of the renal device for controlling the neutrality of the blood, and the alveolar air, by which the pulmonary regulatory device is judged, all need to be studied in any fundamental investigation of the dyspnea encountered in cardiac and renal disease. A good beginning in this direction has been made at the Peter Bent Brigham Hospital in Boston by Dr. Francis W. Peabody.[3] As he has pointed out, it is quite possible that different causes for the dyspnea in various types of uncomplicated heart disease may be ascertained, and the study of large numbers of cases may lead to the recognition of definite groups of functional derangement.

In uncomplicated cases of chronic nephritis the mild acidosis which is a frequent accompaniment is taken care of by the kidneys as a rule. According to Peabody, it is only in uremia and usually only in very advanced uremia that non-volatile acids accumulate in the blood in an amount sufficient to cause depression of the tension of carbon dioxid in the alveolar air. In the terminal stage of uremia there may be a high grade of acidosis. The development of acidosis is not the direct or sole cause of dyspnea associated with cardiorenal disease. A high grade of acidosis may exist without causing a change in respiration which is evident on the ordinary clinical examination. In some cases of cardiac disease accompanied by dyspnea there is evidence of a slight accumulation of non-volatile acids in the blood. In other cases there is no evidence of such an accumulation. The hydrogen ion concentration of the blood remains normal.

Peabody has shown groups of cases in which the degree of acidosis is not sufficient to account for the dyspnea on the basis of an increase in the stimulus to respiration alone. He concludes that an important factor in the causation of dyspnea in cardiac disease is an increase in the excitability of the respiratory center. Such a change in excitability may well be caused by a lowering of the oxygen tension, and be dependent on an inadequate blood-flow. There may, of course, be developed some as yet unknown substance which affects the stimulus. Until the excitability of the respiratory center under pathologic conditions has been experimentally studied, we may accept the hypothesis tentatively advanced involving the consequences of a poor circulation and possibly a partial oxygen want at the respiratory center. In combined cardiorenal disease, the dyspnea would thus be a circulatory feature, the renal condition playing only an accessory part.

THE HIGH-CALORY DIET IN TYPHOID FEVER

The fear has at times been expressed that the administration of large amounts of food during the febrile stage of typhoid fever may cause too great an increase in heat production and in turn a rise in temperature. From a purely clinical point of view von Hoesslin[1] long ago doubted this possibility. The modern conception of the specific dynamic action of the foodstuffs in metabolism has, however, again given some justification for the reconsideration of the question. It is now admitted that the total metabolism of normal individuals is raised after the taking of food when the latter is furnished in quantities larger than the "basal" requirement. If, for example, the energy metabolism of a subject at rest and without food is determined, the administration of a diet just equivalent to the requirement thus ascertained will not suffice to maintain the usual energy balance. The metabolism of the ingested foods results in raising heat production; and this is the phenomenon of the specific dynamic action of the foods, so called by Rubner.

Whether or not the increase in heat production becomes evident depends on the environment. So long as the chemical regulation of body temperature is called into play, the extra heat liberated may compensate for heat which might otherwise be liberated from other sources in the body; but in the absence of chemical regulation, that is, at temperatures (above 30 C. or 86 F.) at which physical regulation alone suffices for this function, the excess of heat production associated with liberal intake of food comes plainly into evidence. The proteins in the diet are by far the most potent factors in leading, under appropriate circumstances, to a liberation of energy considerably larger than that evoked by the non-protein foods.

The possibility of the exhibition of a specific dynamic action of food in typhoid fever as a consequence of the high-calorie diets which have of late again found favor in this country has to be reckoned with. The undue production of heat incident to the taking of exceptionally large amounts of food during the febrile stage would be far from desirable. In a careful series of measurements made in the Bellevue Hospital of New York, Coleman and DuBois[2] have found that in typhoid fever the liberal diets proposed by Coleman and his collaborators[3] occasion only a slight, if not negligible increase in heat production. It was quite unexpected to find that the large amount of food administered exhibits little or no specific dynamic action. In explanation of this result it is suggested that the stimulation of metabolism by the toxic agent is so intense that further stimulation by food is insignificant. The chief theoretic objection to the use of the liberal diet in typhoid fever is thus set aside.

Current Comment

A NEW JOURNAL ON SOCIAL HYGIENE

The American Social Hygiene Association, recently organized through the amalgamation of several independent organizations, has taken a position that indicates that it is soon to become recognized as the dominant organization working for social and sex hygiene. As one of its activities, the association has established *Social Hygiene*, a quarterly, the first number of which has just appeared. In it President Eliot sets forth the motives and purposes of the association, stating that the first work to be undertaken is that of ascertaining present conditions as regards sexual vice in American cities and towns; next, to study the various sorts of police action against vice and the statutes intended to control it; third, to devise and advocate effective control and legislation; and fourth, to cooperate with other organizations working along similar lines. President Eliot regards as one of the most difficult but indispensable tasks of the association the bringing about of a serious change in the ethics of the medical profession, particularly the attitude of the physician regarding knowledge on venereal infections gained from patients as a matter of professional confidence. While he admits that "in times past the faithful keeping by the physician of the confidences of his patient has been a fine element in the ethics of the profession," he also feels that "the recent discoveries in regard to the contagion, duration and far transmission of venereal diseases have made it necessary to put limitations on a physician's pledge of secrecy, lest he become a silent participant in one of the worst of crimes." Other articles discuss the red light abatement law, the legal protection of matrimony from disease, the regulation of prostitution in the United States, the relation between education and the social hygiene movement, the interest of life insurance companies in social hygiene, etc. Law notes, book reviews, abstracts and news items complete an interesting publication. If the present high purposes and plans of the American Social Hygiene Association can be realized, the organization will prove of enormous benefit to social and public health conditions in this country.

THE ODOR OF THE URINE—"URINOD"

The odor of the urine is *sui generis.* When the secretion from the kidneys is freshly voided it is comparatively odorless in distinction from the condition that develops on standing. Numerous known volatile substances have been described to occur in the urine both normally and under exceptional circumstances. Some of them are not free at first, but are gradually liberated by the chemical changes which may arise in the voided fluid. Known exceptional substances which have their origin in the diet or therapeutically administered materials are not included here. Drs. Dehn and Hartman[1] of the Chemical Laboratory at the University of Washington in Seattle have set up the thesis that hitherto known volatile substances of the urine are not responsible for its characteristic odor. Some of these, as ammonia, indol and possibly phenols, contribute to the composite nature of the odor. Dehn and Hartman believe that they have discovered the product which imparts to all urines their characteristic odor and which has apparently been overlooked by previous investigators. The newly found substance, which they name urinod,[2] occurs to the extent of only 1 or 2 parts in 100,000 parts of urine. This fact is made to account for the failure of a previous recognition and also indicates why the search for it has been so laborious. Quantities of urine as large as 1,000 liters (quarts) were manipulated in attempting to isolate the urinod. As a result a neutral, ill-smelling substance, with the empiric formula C_6H_8O, has been separated from the fluid. Its structural formula has even been suggested, and we are told that it occurs in urine in the conjugated form and is set free by fermentation. Urinod seems to be excreted in all samples of urine, and since it is found constantly, like urea, uric acid, etc., the discoverers believe that it must bear some relation to metabolism. According to Dehn and Hartman, the odor of urine, though largely caused by urinod, is blended with basic, acidic, phenolic and other neutral compounds, under different conditions of alkalinity, acidity and neutrality. Since urinod is not found in fresh urine in the free state, its offensive odor is not developed unless urine is permitted to ferment, is evaporated or ignited, is treated with acids or alkalies, or is secreted under pathologic conditions. It is well known that urea and other urinary compounds occur in small quantities in perspiration; and it is now suggested that some derivative of the newly heralded urinod or the urinod itself may also be excreted by the skin. The product is said to resemble the so-called body odor and may thus be a factor in the composite odor of ill-ventilated rooms occupied by man.

THE INFECTIONS ON IMMIGRANT SHIPS

Under present regulations, ships having on board such diseases as scarlet fever and measles are not held at the maritime quarantine stations. Williams[1] says this is especially unsatisfactory with reference to immigrants arriving by sea, among whom the children often develop infectious diseases while on shipboard. Many persons are then exposed to the contagion, are landed and later develop these diseases in communities to which they go. Of the immigrants arriving at Ellis Island, for instance, many (in 1913, 87 per cent.) land and proceed at once to their destinations. Among those detained for various reasons it is found that infectious diseases frequently develop, a majority falling ill within the period of incubation of these diseases as calculated from the date of landing, indicating that they were infected on shipboard. These outbreaks occur so regularly that it seems reasonably certain that the same thing happens among those not detained. For the year ended June 30, 1913, out of 834 patients with measles admitted to the Contagious Disease Hospital at Ellis Island, 576 were taken from ships on the day of arrival, and 258 additional cases developed among detained immigrants subsequent to arrival. Of the latter number, 167 fell ill within a period after arrival indicating that they had been infected on board. These 167 cases developed among the 13 per cent. of immigrants detained. At the same rate among the 87 per cent. not detained there would have occurred 1,117 cases of measles, distributed wherever these immigrants scattered themselves, each case becoming a possible focus for the further spread of the disease. Fifty-six cases of scarlet fever developed among the 13 per cent. of detained immigrants, which, with a like calculation, would give 375 cases among the 87 per cent. of those not detained. The possibilities of the spread of these dangerous infections from this source are therefore great. Williams suggests as a remedy the proper isolation and handling of the cases on board ship, which is not at present carried out. Of the 576 cases of measles referred to, only 70 per cent. were "manifested" on the ship surgeon's report, while the other 30 per cent. were discovered only on examination at Ellis Island.

THE ASSIMILATION LIMIT FOR GALACTOSE

We have repeatedly urged caution in the strict interpretation of chemical tests for functional disorder in all cases in which the physiologic basis of the reaction involved was not yet clearly understood and the character of the response admittedly far from specific for the disturbance under observation.[2] Among recent methods in this field of clinical examination the determination of tolerance to different sugars has come into vogue. Glucose, levulose and galactose each has had its turn, and criteria of dosage have become established for each sugar. Thus 100 gm. of levulose or 40 gm. of galactose, respectively, have been employed of late in determining the tolerance of individuals in cases of suspected disease in which the assimilation limit for these carbohydrates is known to be depressed by some associated disturbance of function. In Goldscheider's polyclinic at the University of Berlin, Hoffmann[3] has reinvestigated the tolerance of human subjects for galactose, not only observing the excretion of sugar in the urine as an index of the limit, but likewise examining the sugar content of the blood and thus making use of the most recent of the methods of ascertaining the behavior of carbohydrates in the organism. On the basis of his findings he has concluded that in man the normal limit of tolerance for galactose is decidedly lower than it has hitherto been placed. He gives 15 gm. as a lower figure in place of 40 gm., originally proposed by Bauer[4] in von Neusser's clinic. This might seem like an inconsequential matter were it not true that estimation of the onset of alimentary galactosuria is actually being used for diagnostic purposes by some American clinicians at the present time. It is, therefore, highly important that the norm in the phenomenon should be correctly ascertained.

HEALTH BOARDS AND THE TAXPAYER

Appropriations for health purposes in many communities have in the past been granted reluctantly, and in most instances in insufficient amounts for effective work. It has been difficult to convince the taxpayer and the public official that there would be an adequate return for money expended. Health to them has seemed an individual matter, and health boards have been compelled to beg for every dollar. An improvement, however, is taking place, and the amount per capita of health appropriations is increasing. A more intelligent understanding of the objects of public health expenditures and of the returns to be had is developing. In some instances, the taxpayer is now on the other side of the proposition. He demands of the health board, having approved liberal appropriations, that it prevent epidemics which endanger the health and lives of himself, his family and his friends. Spartanburg, S. C., has been for several years a center for the study of pellagra by a scientific commission. This has no doubt promoted the study of health matters in general in that community, with the result that the local health service has been well supported, while the people have come to recognize the possibilities of disease prevention. With the idea in mind of the seasonal recurrence of certain infectious diseases, the Spartanburg *Herald* says:

> For the amount of money the citizens of Spartanburg are putting up these days for the public health department they have reason to expect service and results. . . . Just at this season of the year and a little later on, in February and March, most cities are visited by . . . scattering cases of diphtheria and epidemics of measles and whooping-cough. Measles and whooping-cough usually spread until they have exhausted the supply of youngsters who have come on since

the last year's epidemic, while diphtheria, because of its more violent character, is usually held in check. But the question in our mind is whether these things have to be. In modern days is there no way to prevent so much suffering and sickness on the part of the little children of a city? The Spartanburg health authorities could in no way carry their services nearer the homes of the people than by making a study of this question and taking every precaution possible to hold these things in check this year.

It goes without saying that the health board of Spartanburg will do its utmost, but this change of attitude of the taxpayer toward disease prevention is interesting and hopeful. It also emphasizes the obligation on the part of health departments to make good.

Medical News

(Physicians will confer a favor by sending for this department items of news of more or less general interest; such as relate to society activities, new hospitals, education, public health, etc.)

ALABAMA

Hospital Dedicated.—The Hospital erected by the Order of the Eastern Star at the State Masonic Home near Birmingham, was dedicated with formal ceremonies, December 2.

Personal.—Dr. Daniel T. McCall has been elected president, and Dr. Harry T. Inge, vice-president of the Mobile City and County Tuberculosis Sanatorium, the organization of which was perfected December 20.——Dr. John Kimbrough, Jr., Mobile, has been commissioned First Lieutenant, M. C., Ala. N. G.

Health Campaign of State and Local Boards of Health.—Dr. Frank V. Meriwether, Gantt, of the State Board of Health, in cooperation with the Lawrence County Board of Health, conducted a health campaign in that county in December, giving stereopticon lectures on typhoid, pellagra and hookworm and a free examination followed by free treatment of hookworm. A large number attended the lectures and took advantage of the treatment.

ILLINOIS

Transfer Insane to New State Hospital.—Thirty-five patients have been transferred from the Anna State Hospital to the new Alton State Hospital, and are quartered in a farm house which has been remodeled and fitted for that purpose.

All Things in Common.—It is reported from Macomb that the physicians of that city have rented a portion of an office building and are attempting to work on a cooperation basis, the instruments of each to be of service to others. They will also place the knowledge of each at the disposal of others, and patients will enjoy the advice and consultation of all, at no additional expense.

Personal.—Dr. Lemuel B. Short, health commissioner of East St. Louis, has also been appointed city physician.——Dr. Harry O. Collins has been appointed a member of the staff of St. Mary's Hospital, Quincy.——Dr. Otis Johnston, Quincy, fell on the ice, December 30, spraining his right ankle.——Dr. Alden E. Smith, Freeport, has been elected president and Dr. Sara E. Hewetson, Freeport, secretary, of the Stephenson County Antituberculosis League.——Dr. William G. Schmidt, Quincy, is reported to be critically ill.

Chicago

Medical Women Hear Coroner.—At a meeting of the Medical Women's Club, January 13, Coroner Peter M. Hoffman of Cook County delivered an address on "Public Safety."

Tuberculosis Advisory Committee Appointed.—On December 21, the president of the Board of Cook County Commissioners appointed the following advisory committee for the tuberculosis hospitals of Cook County: Drs. Theodore B. Sachs, Ethan A. Gray and Stephen R. Pietrowicz, and Mr. James Minnick.

To Study Defective Children.—At a meeting of the Board of Education, January 6, a committee was appointed, consisting of Drs. Peter C. Clemensen, O. F. Warning and Stephen R. Pietrowicz, to cooperate with Daniel P. MacMillan, director of the Child Study and Educational Research Department, to assist that department in the scientific study of the defective child.

Personal.—On January 7 twenty-five members of the staff of the Illinois Charitable Eye and Ear Infirmary, Chicago, gave a farewell dinner to Charles T. Gerrard, superintendent of the institution for the last sixteen years. Dr. Norval H. Pierce presided as toastmaster, and a silver loving-cup was presented to Mr. Gerrard by Alderman Dr. Willis O. Nance. Dr. James L. O'Connor has succeeded Mr. Gerrard as superintendent of the institution.——The Illinois Society of St. Andrew, at its annual meeting January 8, reelected Dr. John A. McGill president.

INDIANA

Hospital Incorporated.—The Indianapolis Eye, Ear, Nose and Throat Hospital was incorporated with a capital stock of $10,000. It is the outgrowth of a medical clinic which has been conducted for some time at the Hillside Christian Church.

Tuberculosis Foes Meet.—At the annual meeting of the Fort Wayne Antituberculosis Society, December 30, Dr. Eric A. Crull was reelected medical director and Drs. Charles G. Beall, Adam L. Schneider, Hermann A. Duemling, Eric A. Crull and Edmund M. Van Buskirk were elected members of the executive committee.

Whole-Time Health Officers.—The Indiana Federation of Clubs has petitioned the state legislature to pass a law requiring all health officers to be trained officials, giving their entire time to the work and providing that they be placed under civil service rules so that they may not be removed under political reasons.

Personal.—Dr. Brown S. McClintic, Peru, on duty with the Russian Red Cross, is now stationed at Kiev.——Dr. Norman E. Jobes, former superintendent of the Indianapolis City Hospital, has been given a verdict by the appellate court for $2,450 against the city of Indianapolis for services rendered as superintendent for the Hospital for Contagious Diseases.——Dr. Charles Bowman, New Albany, is reported to be critically ill at his home.——Dr. Louis Burckhardt has resigned as a member of the attending staff of the Indianapolis City Hospital.——Dr. Henry W. Gante, Anderson, who has been seriously ill with diphtheria, is reported to be improving.

KENTUCKY

Medical Club Incorporates.—The Louisville Medical Club filled out articles of incorporation December 11, and the officers named on the papers are: Drs. Peter S. Ganz, president; Michael Casper, vice-president; Arthur M. Barnett, secretary, and Bernard J. Lammers, treasurer, all of Louisville.

Thousands for Sanatorium.—The executive committee of the Louisville Antituberculosis Association reports that by its sale of Christmas seals in the interest of Hazelwood Sanatorium, $3,000 has already been received and it is believed that $2,000 additional will be raised before the conclusion of the campaign.

Personal.—Dr. Milton Board, Louisville, has been appointed registrar of vital statistics of the Louisville district, succeeding Dr. William E. Gary.——Drs. Lewis S. McMurtry, Louisville; Hugh N. Leavell, Louisville, and William E. Gardner, Lakeland, have been appointed members of the Jefferson County Board of Health.——Dr. Jesse I. Whittenberg, Louisville, has been elected health officer of Jefferson County, vice Dr. Benjamin W. Smock, deceased.——Dr. John M. Morris, Louisville, fractured his right arm January 1, while cranking his automobile.——Dr. Richard B. Cassady, LaGrange, is reported to be seriously ill with jaundice.

MAINE

School Medical Inspection.—During the first year of the act providing for the appointment of school physicians, 49 were employed and 87,000 children were given the tests as to sight and hearing. During 1914 examinations were more generally and effectively given and 114,529 children were given the same tests with the result that 11,980 were found to have defective vision, 44 being totally blind and 3,673 having defective hearing. During the year, 52 school physicians were employed, at an average cost of less than $100.

Physicians in State Legislature.—Twelve physicians of the state have been elected members of the seventy-seventh legislature. Of these, five are in the Senate, Drs. Aaron J. Fulton, Blaine; Alonzo M. Garcelon, Lewiston; Harry M. Multon, Cumberland Center; G. Gilmore Weld, Oldtown, and Wallace N. Price, Richmond. The medical members of the house of representatives are Drs. Richard T. Leader, Lewiston; Albert W. Plummer, Lisbon Falls; Augustine B. Libby, Smyrna Mills; Isaac D. Harper, South Windham; Elmer J. Morrison, Bar Harbor; Cecil E. Wasgatt, Deer Isle, and Adelbert Millett; Belfast.

MASSACHUSETTS

Harvard to Have Hospital Unit in Paris.—Harvard University has raised about $10,000 to equip and maintain a hospital unit at the American Hospital, Paris, to assist in caring for the wounded in the war. The unit will consist of two resident surgeons, three interns, two operating nurses and two anesthetists.

Tuberculosis Hospital Dedicated.—On January 2 the Carter Memorial Tuberculosis Hospital at Lancaster erected according to the wishes of Miss M. Elizabeth Carter in memory of Charles M. and Martha Howard Thurston Carter, was formally dedicated and the keys were presented to the Clinton Hospital Association. Addresses were made by Governor Walsh and Dr. Walter P. Bowers, Clinton. After the exercises the hospital was opened for inspection by the public.

Mental Hygiene Society Organized.—The Massachusetts Society for Mental Hygiene has been organized with the aim of educating the people as to the real cause of the disease and to give instructions in plain and tested measures for the prevention of mental diseases, the officers of which are: Hon. Harvey H. Baker, Boston, president; Dr. Walter E. Fernald, Waverly, vice-president; Dr. Charles E. Thompson, Gardner, secretary; John Keran, Boston, treasurer, and Dr. Frankwood E. Williams, Boston, executive secretary.

Personal.—Dr. Richard P. Strong, professor of tropical medicine in Harvard Medical School, has been appointed director of hospitals, laboratories and research work of the United Fruit Company. His new field of labor will be in the West Indies and Central and South America.——Dr. John J. Dowling, Boston, has been appointed superintendent of the Boston City Hospital, to take effect January 31, vice John H. McCollom, Boston, resigned. Dr. McCollom has been connected with the hospital for 46 years.——Dr. William J. Sullivan has been appointed city physician of Lawrence, vice Dr. George W. Dow——Dr. Charles J. Downey, Springfield, has been named as trustee of the state hospitals for consumptives.

Hospital Efficiency.—On January 6 a meeting for the discussion of hospital efficiency was held at the Boston Medical Library under the auspices of the surgical section of the Suffolk District Medical Society. The general subject of discussion was on whom the responsibility for medical and surgical efficiency, in a charitable hospital, should rest and the general consensus of opinion appeared to be that the responsibility would be vested in a committee composed of representatives of all departments, namely, the trustees, the staff, and the administration. The subject was discussed by Mr. Frank B. Gilbreth, Providence, R. I., from the standpoint of an efficiency expert; by Dr. Robert L. Dickinson, surgeon and gynecologist to the Brooklyn Hospital, from the standpoint of a hospital surgeon; by Dr. Herbert B. Howard, superintendent of the Peter Bent Brigham Hospital, from the standpoint of a hospital superintendent; by Drs. Walter Wesselhoeft of the Massachusetts Homeopathic Hospital and Joel E. Goldthwait of the Peter Bent Brigham Hospital, from the standpoint of hospital trustees, and by Major James M. Curley, from the standpoint of a public servant.

MISSOURI

Centralia Physicians Organize.—The Centralia Medical Association was organized, December 17, with Dr. William A. McAllister, president, and Dr. Orpheus B. Mayes, secretary, both of Centralia.

Colored Medical Association Incorporated.—A pro forma decree of incorporation has been issued at St. Joseph to the Missouri Pan Medical Association, whose officers are: Dr. J. E. Perry, Kansas City, president; Dr. R. Leon Hall, secretary; and Dr. William S. Carrion, treasurer.

Physicians' Club Leases Quarters.—The recently organized Physicians' Club of Springfield has leased space on the third floor of the Woodworth Building as its headquarters. There is one large room, which will seat more than 100 persons, where the meetings of the club will be held, and a smaller room, which will be used as a library and rest room. It is the purpose of the club to invite the Greene County Medical Society to meet with it.

Advise Reorganization of Hospital.—The special committee of the Jackson County Medical Society, consisting of Drs. Edward W. Schauffler, Francis M. McCallum and Andrew W. McAlester, Jr., all of Kansas City, appointed to investigate conditions of the General Hospital, made its report January 4, advising a thorough reorganization, closing with the following words: "This committee begs to be discharged until such time as the medical profession determines to take a positive stand for right and justice to itself and to the public in the administration of this public institution."

Personal.—Dr. Walter S. Wheeler, health commissioner of Kansas City, underwent operation at Wesley Hospital, January 4, and is reported to be doing well.——Dr. George A. Nash, Maryville, who was operated on December 14 for appendicitis, is said still to be in a serious condition.——Dr. William H. Hays, Hannibal, whose leg was amputated as the result of a gunshot wound while on a hunting expedition, is now out of danger.——Dr. Stephen D. Reynolds, Gower, has been appointed a member of the staff of the State Hospital No. 3, Nevada, vice Dr. Charles B. Simcoe, deceased.

The Missouri Foundation for Health Conservation, St. Joseph, Mo.—On December 21, the secretary of state of Missouri issued articles of incorporation to "The Missouri Foundation for Health Conservation," the purposes of which are "the conservation of health and the prevention of disease to the end that human efficiency may be increased and human suffering prevented." Its purposes are to be secured by any means "that demands of time or of science may require." The first activity undertaken will be a medical laboratory to be established at St. Joseph, with its tributary population of 1,000,000. It is intended that this institution shall be a clearing-house where all doctors living in the country tributary to St. Joseph may send specimens from patients for analysis and get prompt returns. The work will be financed by fees, donations, subscriptions and bequests, its aims being scientific, social and benevolent and not commercial. In addition to the medical laboratory, other activities for health conservation will be inaugurated. The secretary of the foundation is Dr. Daniel Morton, St. Joseph, and the members of the board of control are prominent citizens of St. Joseph and the state.

St. Louis

Auditorium Dedicated.—The Auditorium of the St. Louis Medical Society has been rededicated as the Hugo W. Bartscher Memorial Hall, on account of the bequest made to the society by the will of Mrs. Bartscher. An oil painting of Dr. Bartscher will be hung in the hall.

Hospital Quarantined.—On account of eight cases of small-pox at the Lutheran Hospital, the institution has been placed under quarantine. The inmates have been ordered to be vaccinated. Six persons suffering from small-pox were removed from the institution to the Koch Hospital, January 6.

Personal.—Dr. Malcolm A. Bliss, while crossing the street January 6, was knocked down by a motorcycle and seriously injured.——Dr. Leo Loeb, pathologist to the Barnard Free Skin and Cancer Hospital, has resigned, to take effect April 1.——Fire in the house of Dr. William E. Sauer, December 14, did damage to the extent of about $1,000.——Dr. Percy Carroll, a member of the staff of the City Hospital, was operated on for appendicitis, December 21.——Dr. John Young Brown bought a 30-acre tract near Baldwin, Mo., as a site for his country home.

NEW YORK

A Primer for Mothers.—The Buffalo Department of Health has issued for free distribution a four-page "Primer for Mothers," giving general rules for the management of infants.

Scarlet Fever in Children's Home.—An outbreak of scarlet fever is reported from the Cripples Home of St. Giles near Garden City, L. I. The cases are mild and there is little apprehension of serious developments.

Deporting Alien Insane.—Although the work of deporting alien insane has been greatly hampered by the war, there were returned to their native countries either at the expense of the state or of their friends last year 426 alien insane, who had resided in this country for a period of over three years, and who were not deportable under the provision of the immigration law. The number returned to Europe during the previous year was 486.

New York City

New Maternity Hospital Opened.—The Bronx Maternity Hospital Clinic was formally opened January 4 and is now ready for the reception of patients. This is the first maternity hospital established in the Bronx and is entirely the result of private charity.

Harvey Society Lecture.—The sixth lecture of the Harvey Society series given at the New York Academy of Medicine, January 16, is by Dr. Edward R. Baldwin of the Adirondack Cottage Sanatorium, Saranac Lake, on "Immunity in Tuberculosis with Special Reference to Racial and Clinical Manifestations."

Personal.—Dr. James M. Wicks of Jamaica, L. I., who has been working for three months in the American Ambulance Hospital at Paris, has returned to this country.——Dr. Charles F. Stokes, Washington, D. C., Surgeon-General of the Navy under the Roosevelt and Taft administrations, has been appointed superintendent of the city farm colony for inebriates in Orange County.

Drug Arrests.—A special report made to Police Commissioner Woods shows that in 1914, 1,950 arrests were made by the special squad which was organized to break up the illicit sales and distribution of drugs and narcotics. It is said that in 1913 there were 511 arrests on similar charges. In 1914 there were 947 convictions secured as against 256 in 1913. The report is said to show a great improvement over previous conditions.

Hungry Schoolchildren to Be Fed.—Beginning January 11, twenty-four restaurants will be started in the public schools of the greater city. Superintendent Maxwell announces that he has at present $9,000 with which to start the project, and Andrew Carnegie has promised $2,000 provided an additional $10,000 is raised. A portion of any article on the menu will be furnished to a pupil at one cent and free tickets will be distributed to those unable to pay.

New York Leads in Tuberculosis Fight.—The annual statement of the National Association for the Study and Prevention of Tuberculosis shows that during the past year more than $20,500,000 was spent in the tuberculosis campaign in this country, and that New York has spent more during the past year than any other two states. Illinois has second place. The statement also shows that 66 per cent. of the money was derived from public funds, either federal, state, county or municipal, while the remainder was contributed by private philanthropy.

Academy of Medicine Meeting.—The annual meeting of the Academy of Medicine was held on January 7, at which time the reports of the officers and committees of the academy were presented. The treasurer's report shows the academy in a thriving condition financially. The trust funds now total $687,090. The most interesting report was that of the public health, hospital and budget committee which shows the wide variety of activities in which the academy is interested. The executive session was followed by the retirement of the president, Dr. William M. Polk and the inauguration of his successor, Dr. Walter B. James.

NORTH CAROLINA

Nurses' Home.—The Presbyterian Hospital, Charlotte, has leased a building adjoining the hospital for use as a nurses' home.

Free Clinic.—A free clinic has been established at the Spencer Sanitarium, Winston-Salem, with the cooperation of fifteen or twenty physicians of the city. The clinic will be opened from 12 to 2 p. m., Mondays and Saturdays being set aside for colored patients.

Personal.—Drs. George W. Purefoy and Marshall H. Fletcher have been reappointed members of the Buncombe County Board of Health.——Dr. Thomas W. M. Long, Roanoke Rapids, has been appointed a director of the Eastern Hospital for the Insane, Raleigh.

New Buildings for School for Feeble-Minded.—The trustees of the North Carolina School for Feeble-Minded, at the annual meeting held in Kington, recommended an extension of the institution including three buildings and involving an expenditure of $120,000. Dr. C. B. McNairy, was reelected superintendent of the school.

Whole-Time Health Officers.—At the January meeting of the board of aldermen of Winston-Salem, it was voted to organize a complete health department for the city and to secure the services of a competent whole-time health officer. ——The commissioners of Pitt County, at the January meeting, held in Greenville, voted to establish a whole-time county health officer.

PENNSYLVANIA

Personal.—Dr. S. Albert Blair, Chambersburg, has been appointed chief surgeon of the Hospital for Diseases of the Eye, Ear, Nose and Throat, recently opened at Scranton.——Dr. Henson F. Tomb, Johnstown, who was operated on December 23, at the Memorial Hospital, Johnstown, for cholecystitis, is reported to be making good progress toward recovery.

Decrease in Contagious Diseases.—Communicable diseases in Pennsylvania during 1914 were 50,000 less than the number in 1913, according to a statement issued December 31 by Dr. Samuel G. Dixon, commissioner of health. Typhoid fever decreased 70 per cent. The general death-rate was only 14.1 per 1,000 inhabitants. Tuberculosis was reduced, and cancer was the only disease which showed an increase.

Vindication of Physicians.—In a suit brought by Mrs. Ella E. Caldwell of Indiana, against Drs. William A. and George E. Simpson of the same town, alleging that they fraudulently, knowing the plaintiff was not insane, signed an insanity certificate committing her to the Pennsylvania Hospital for the Insane, Philadelphia, the trial judge gave a strong charge in favor of the defendants, who were promptly acquitted.

Philadelphia

Rush Society Lecture.—A change has been found necessary in the program for the Ninth Rush Society Lecture, January 23 next, as Professor Umber of Berlin has found he would be unable to come, because of the war. Dr. Lafayette B. Mendel of Yale University will speak on "Nutrition and Growth."

Personal.—Dr. Richard H. Harte, director of public health and charities, resigned January 6.——Dr. S. Lewis Ziegler has been appointed director of public health charities to succeed Dr. Harte.——Dr. Charles W. Burr has been appointed consulting neurologist to the Municipal Hospital. ——Dr. Howard Kennedy Hill was reelected chairman of the track committee of the University of Pennsylvania, December 21.

Graduate Nurses to Help War Hospitals.—Graduate nurses, meeting at the call of chairman of the Red Cross division of the Emergency Aid Commission, organized December 8 a corps of workers for the manufacture of bandages and other surgical supplies for use on European battle fields.——The "Made In America" Bazaar Committee has $4,000 to turn over to the Red Cross division and a like sum to the Belgium Relief division.

School for Tuberculous Children Open.—Twenty children suffering from symptoms of tuberculosis began school in an open air class-room provided by the board of education, January 4. A small building on the Girard School property at Eighteenth and Snyder Avenue has been thoroughly repaired and improved by the department of buildings. The building is provided and equipped with a kitchen and dining room and philanthropic agencies have been asked to help to start a lunch room. The children will be expected to pay but none will be refused food.

Wet-Nursing Bureau.—The Babies' Welfare Association has organized a central bureau of information concerning all agencies in the city which are conducted for the welfare of infants. Among its other activities the association is attempting to put into operation a plan for the centralization of wet-nursing in the Bureau of Health. The central office has a registry for wet nurses desiring positions, as well as one for physicians who wish the services of wet nurses. Every candidate for wet-nursing is required to present a certificate of general physical fitness. No candidate is considered available until the Wassermann test has been submitted to and the result of the examination has been returned negative.

GENERAL

Revenue Cutters to Carry Surgeons.—An order has been issued by the Secretary of the Treasury that each revenue cutter engaged in winter cruising on the Atlantic Coast, shall carry a surgeon of the Public Health Service. This action is in addition to that noted last week in The Journal.

of the equipment of the Revenue Cutter *Androscoggin* as a hospital for sick and injured fishermen.

Memorial for Theobald Smith.—On account of the impending severance of his connection with Harvard University after a service of twenty years, the colleagues of Professor Theobald Smith are arranging for a permanent memorial. It is proposed to present a bas-relief of Professor Smith to the medical school and reductions of this will be made and presented to each donor of $10 or more to the fund. A complimentary dinner is to be given to Professor Smith on April 17, the cost of which will be $5 per cover. Subscriptions should be sent to Dr. Marshall Fabyan, 379 Commonwealth Avenue, Boston, not later than February 10.

Bequests and Donations.—The following bequests and donations have recently been announced:

The Episcopal Hospital, Philadelphia, $10,000 by the will of John Dobson.

Germantown Dispensary, $2,100 by the will of Margaret McLain.

Chestnut Hill Hospital, Philadelphia, $1,000; Howard Hospital, Philadelphia, $22,000 by the will of Anna F. Brush.

Harvard Medical School, $50,000 for the endowment of a chair of gynecology to be known as the William H. Baker Chair of Gynecology, by the will of Dr. William H. Baker, of Waltham, in the event of Harvard Medical School not desiring to accept the bequest under the conditions named, it is to be turned over to the Free Hospital for Women, Brookline.

Philadelphia County Medical Society, for its beneficent activities, $5,000 by the will of Dr. Louis A. Duhring.

New York Infirmary for Women and Children, $6,000; State Charities Aid Association, $25,000 by the will of Grace Hoadley Dodge.

Plague Work in New Orleans.—Up to December 26, the public health officials, engaged in work against the bubonic plague in New Orleans, report that 205,872 rodents had been captured, 178,421 of which had been examined. Of these, 213 were found to be infected. The infected rats by species were as follows: Mus Rattus, 11; Mus Musculus, 1; Mus Alexandrinus, 5, and Mus Norvegicus, 196.——During the week ended January 2, 17 vessels were fumigated with sulphur; 14 with carbon monoxid and 2 with hydrocyanic gas; 26 clean bills of health and 12 foul bills of health were issued; 237 cars were inspected and 9,359 rats were trapped; 5,092 rodents were examined out of 9,481 received at the laboratory and of these, 43 were suspicious and in 6 cases the diagnosis of plague was confirmed. Up to the present time 219 plague rats have been discovered.

Gorgas Medal Established.—The Gorgas Medal to be given yearly in honor of Surgeon-General Gorgas has been established by the Medical Reserve Corps, U. S. Army, New York State Division. This medal is open to competition to members of the Medical Corps of the United States Army, the Medical Reserve Corps of the United States Army and to members of the medical corps of the organized militia. Officers may submit papers on any subject of a medico-military nature. General Gorgas has appointed the following board of officers to act on papers submitted: Colonel Charles Richard, Lieut. Col. Champe C. McCulloch, Jr., and Major Eugene R. Whitmore, Army Medical Corps. These officers are members of the faculty of the Army Medical School and will have sole authority to appoint the time that papers are to be submitted, and to pass on the merits of the papers. All inquiries should be addressed to one of these officers.

Inspection of Schoolchildren in Canal Zone.—District physicians have been instructed to follow up the cases of all children found infected in the physical examination recently given to pupils in the Canal Zone public schools. After the expiration of thirty days, the physicians are to advise the chief health officer what percentage of those previously found infected report for treatment, together with results obtained. Teachers have been requested to inform the district physician when pupils have been absent for unknown causes, in which case the physician will visit the homes of pupils and institute such measures which may be deemed necessary.——District physicians, together with the health officers of Panama and Cristobal-Colon, have been instructed to visit all schools in their respective districts and to vaccinate all pupils who have not had small-pox, or who have not been successfully vaccinated within the last five years, issuing certificates to all pupils and teachers whom they vaccinate.

State Child Welfare Exhibits.—Plans are under consideration involving the cooperation of the state departments of health, charities, education, labor, etc., for the holding of child welfare exhibits, under the direction of the extension divisions of the state universities. Among the states having the plan under advisement are Indiana, Arkansas and Oklahoma, and Wisconsin, Missouri, Nebraska, Kansas, Iowa and Minnesota have decided on exhibits and are awaiting organizers from the National Child Welfare Exhibit Association. The exhibits would comprise the propaganda work of the various state departments named as it affects children, with the object of showing constructively what is being done for the children by the various states and what it is necessary to do. In the past few years successful exhibits have been held in the larger cities, and the idea has been taken up by various cities abroad. The experience of the United States was called on in preparing these latter exhibits. Charles F. Powlison, 200 Fifth Avenue, New York City, is secretary of the National Child Welfare Exhibit Association. He seeks correspondence with and cooperation of experts in various lines of child-helping.

Conferences on Medical Education, Legislation and Licensure.—During the three days February 15, 16 and 17, there will be held at the Congress Hotel, Chicago, a series of conferences on medical education, medical legislation and the licensing of physicians. On Monday, February 15, the Council on Health and Public Instruction of the American Medical Association will hold its regular annual conference. The program follows:

1. Call to order by the Chairman, Dr. Henry B. Favill.
2. Chairman's Address.
3. Secretary's Report.
4. Report of the Committee on Medical Expert Testimony. Prof. E. R. Keedy.
   Discussion:
   Dr. Harold N. Moyer.
   Prof. John H. Wigmore, Chicago.
   Judge Albert C. Barnes, Chicago.
   Judge Harry Olsen, Chicago.
5. Presentation and Discussion of Bill for the Prevention of Ophthalmia Neonatorum.
6. Model Bill on State Public Health Organization. Dr. Henry M. Bracken, St. Paul.
   Discussion:
   Dr. J. N. Hurty, Indianapolis, Ind., Secretary State Board of Health.
   Dr. S. J. Crumbine, Topeka, Kan., Secretary State Board of Health.
   Dr. George B. Young, Commissioner of Health, Chicago.
   Prof. Charles Henderson, University of Chicago.
   President George Vincent, Minnesota State University.
7. State Regulation of Those who Treat the Sick. Hon. G. H. Hodges, Governor of Kansas.
   Discussion:
   Dr. George H. Cook, Natick, Mass., President Conference of State Examining and Licensing Boards.
   Mr. A. C. Umbreit, Milwaukee.
   Dr. A. D. Bevan, Chicago, Chairman Council on Medical Education.

On Tuesday, February 16, the Council on Medical Education will hold its eleventh annual conference. The program follows:

1. Opening of Conference by the Chairman, Dr. Arthur Dean Bevan, Chicago.
2. Report of the Secretary, Dr. N. P. Colwell, Chicago.
3. Report of the Committee on the Reorganization of Clinical Teaching, by the Chairman, Dr. Victor C. Vaughan, President, American Medical Association, Ann Arbor, Mich.
4. Report of the Committee on Graduate Medical Instruction, by the Chairman, Dr. Horace D. Arnold, Dean of the Graduate School of Medicine of Harvard University, Boston, Mass.
   Discussion: Dr. James F. McKernon, President of the Faculty of the New York Post-Graduate Medical School, New York City.
5. Symposium on Higher Degrees in Medicine.
   (a) "The University and Higher Degrees in Medicine," by President George E. Vincent of the University of Minnesota, Minneapolis, Minn.
   Discussion: President Harry Pratt Judson of the University of Chicago, Chicago.
   (b) "Courses and Degrees in Public Health Work," by Dr. Milton J. Rosenau, Professor of Preventive Medicine and Hygiene, Harvard University Medical School, Boston, Mass.
   Discussion from the Engineer's Standpoint—Mr. M. C. Hoad, Professor of Sanitary Engineering, University of Michigan, Ann Arbor, Mich.
   (c) "Preparation of Specialists in Ophthalmology and Oto-Laryngology," by Dr. Frank C. Todd, Professor of Diseases of the Eye, Ear, Nose and Throat, University of Minnesota, Medical School, Minneapolis, Minn.
   Discussion—Dr. Edward Jackson, Professor of Ophthalmology, University of Colorado, School of Medicine, Denver, Colo.
   (d) "Higher Preparation in Surgery," by Dr. John M. T. Finney, Professor of Clinical Surgery, Johns Hopkins University, Medical Department, Baltimore, Md.
6. "A Scheme Facilitating More General Licensure," by Dr. W. L. Rodman, President-Elect of the American Medical Association, Philadelphia, Pa.

On Wednesday, February 17, there will be a joint conference of the Federation of State Medical Boards of the United States and the Association of American Medical Colleges. The program follows:

1. "Some Thoughts on the Work of the State Board of Medical Examiners," John Huston Finley, LL.D., Commissioner Education, State of New York.

2. "Classification of Medical Colleges," Henry S. Pritchett, President Carnegie Foundation.
3. "Fallacies in the Argument Against Full Time Clinical Instructors," Major J. Seelig, St. Louis, Mo.
4. "Minimum Expense of Maintenance of an Acceptable Medical College," Laboratory Department, F. C. Waite; Clinical Department, John L. Heffron.
5. Address of President (subject not announced), Isadore Dyer, New Orleans, La.

FOREIGN

The Prohibition of Absinthe Not Enforced in France.—The recent decree forbidding the sale of absinthe in France failed to forbid renewal of supplies. The saloon-keepers are thus able to keep their stock replenished, and the daily paper, *le Temps*, hints that the clandestine consumption of absinthe is being encouraged by the administration. At a recent meeting of the Société méd. des hôp., a vigorous protest was unanimously voted calling on the authorities to enforce "the regulations against this redoubtable foe in our midst," and make them definitely prohibitive.

Deaths in the Profession Abroad.—The cable brings word of the death of Klaus Hanssen, physician in chief of the Bergen Public Hospital, Bergen, Norway, and leader in the campaign against tuberculosis, aged 71.——S. Gottschalk, privat-docent of gynecology and obstetrics at the University of Berlin, founder of a private clinic, and author of numerous articles on chorio-epithelioma, etc., aged 54.——E. Mairinger and J. Zuckermann, both of Vienna.——The death is also reported of Wilhelm Hittorf, professor of physics at the University of Münster, and not a member of the profession, but Hittorf's work on the cathode rays blazed the way for the discovery of the Roentgen rays.

From Bahia, Brazil.—The professor of histology and chief of one medical clinic connected with the University of Bahia, Prof. Pacifico Pereira, for nearly half a century has been a leading spirit in medical education and public hygiene. He founded in 1866 the *Gazeta Medica de Bahia* and has edited it since. On the occasion of his recent retirement from his chair on account of having reached the age limit, an ovation was tendered him, a festival under the auspices of the medical department, with representatives from scientific societies throughout Brazil and beyond.——The University of Bahia was founded in 1808 but still has only the "faculty of medicine, surgery and pharmacy" as when first founded. It has forty-two professors besides over a dozen assistants, and there were 730 students enrolled in 1913.

Prizes Distributed by the Paris Academy of Medicine.—The Académie de Médecine is the medical department of the National Institute of France, and it has seventy-three endowments for prizes to be awarded in the medical sciences. Of the forty-three available in 1914 and which have just been distributed, fourteen could not be awarded as in the case of the Audiffred prize which offers a capital representing an annual income of $4,800 for a "sovereign remedy against tuberculosis." Of the six articles offered in competition, only one was given "encouragement" with an award of $200 for research on the tubercle bacillus. The Roussilhe prize was awarded for the first time. This is a triennial prize of $2,000 for the "greatest progress in dermatology for the relief or cure of diseases of the skin." Competition is open to all scientists, French or foreign. The prize was given to Professor Gougerot of Paris for his works on skin diseases, especially his research on sporotrichosis. The prize of $200 for the "most meritorious medical student" was given to Mademoiselle Romme. The only one of the prizes ($240) which went out of France was given to H. Fredericq of the University of Liége for his research on the comparative physiology of the circulation. All of the prizes except seven are open to foreign competition. The Académie prize of $200 is offered in 1915 for the best work on diabetic coma; in 1916, on hemoglobinuria; in 1917, on paralysis of the recurrent nerve. The issue of the *Bulletin*, Dec. 15, 1914, contains the conditions and details of the entire list of prizes offered in the next three years.

WAR NOTES

Losses Among the German Medical Officers.—The *Medizinische Klinik*, December 13, says that of the regular army and navy medical corps only one physician has been reported as disabled from sickness since the war began; forty have been severely and 112 slightly wounded; sixty-five have fallen on the field; seventy-eight are missing, and forty-six are known to be in captivity.

Price of Opium in Germany.—Prof. J. Pohl, in an address at Breslau, November 20, commented on the rise in price of opium, saying that the wholesale rate in July was 44 marks and, at the time of speaking, 80 marks per kilogram. This is nearly $37 a pound. He added that this high price was due not only to the fact that importation had ceased, but also to the probability of the next harvest falling short.

Italian Red Cross Hospital at Paris.—There are 100 beds in the hospital organized by the Italian colony in Paris to receive wounded soldiers. The three pavilions form an annex to the Val-de-Grâce military hospital. They were nearly new private houses that have been transformed into a well-equipped modern hospital. The *Policlinico* states that all of the tetanus patients treated there by the Baccelli phenol method recovered.

The Iron Cross for German Physicians.—The *Berliner klinische Wochenschrift* of December 14 states that the Iron Cross has been conferred by the German authorities on 1,500 physicians at the front. The profession rejoices at this appreciation of the devotion of the medical men with the army, especially as it has been less than a year since the medical officers were placed on the same footing in every respect as the other officers in the army and navy.

Aid for Belgian Profession.—The report of the treasurer, Dr. F. F. Simpson, of the committee of American physicians for the relief of the Belgian profession, for the week ending Jan. 9, 1915, lists the following contributions:

E. G. M.	$ 10.00
L. M. W.	5.00
A. T.	10.00
J. G. R. M.	25.00
J. C. T.	25.00
L. C. F.	10.15
E. T. F.	10.15
F. W. S.	10.00
G. L. H.	25.00
G. E. L.	5.00
E. E. K.	10.00
A. M. C. O.	100.00
D. S. M.	10.00
C. M. B.	1.00
M. C. M. S.	25.00
H. M. S.	10 00
E. H. M.	5.00
Total	$296.30
Disbursements	None
Contributions previously reported	$662.50
Grand Total	$958 80

LONDON LETTER

London, Dec. 24, 1914.

The War

THE RED CROSS HOSPITALS IN FRANCE

Sir Frederick Treves, who has returned from a visit of inspection of the Red Cross hospitals in France, has submitted his report to the British Red Cross Society. He speaks highly of the fleet of motor ambulances provided by the society. He thinks it represents the most valuable service ever rendered by voluntary aid to the army medical department. "These ambulances are everywhere. The majority are working at the front in convoys of various sizes. They are perfectly organized and equipped, and are always at work. When they come down with patients they return with stores for the wounded. In the saving of life, in the lessening of suffering, and in the securing of prompt surgical treatment for the wounded these ambulances have done a work the value of which can hardly be exaggerated." In addition to the motor ambulances, the society has many other cars which are of great service in dispatch work and the conveyance of goods. A large number of these have been lent to the society by generous owners. The chauffeur who drove Sir Frederick Treves to Le Touquet was Mr. Kennerley Rumford, the famous singer. Another driver of note is the vicar of a quiet country parish in England.

SERIOUS SHORTAGE OF MEDICAL STUDENTS

The shortage of medical students in consequence of those who have gone to the front as combatants as well as dressers has been mentioned in a previous letter. Actual figures have now been furnished by Sir Donald Macalister, president of the General Medical Council, who finds that the decrease this year as compared with the preceding years is as follows:

first year students, 56 fewer; second year students, 237 fewer; third year students, 237 fewer; fourth year students, 211 fewer; fifth (and higher) year students, 300 fewer. The aggregate number of medical students now pursuing their curriculum with a view to qualification is thus about 1,000 smaller than in 1913. Unless many senior students return to their studies within the next few months, the result will be that the number of young qualified practitioners added yearly to the ranks of the profession will during the next few years be from 200 to 300 less than before. This is equivalent to a diminution of about 25 per cent. of the average number annually added to the medical register on qualification.

AMBULANCE BARGES

Sir Arthur Sloggett, the surgeon-general to the British forces at the front, has approved of and accepted a proposal made by Mr. Douglas Hall, M.P., to procure and equip four ambulance barges for immediate use on the waterways at the seat of war in France and Flanders. As this proposal will entail considerable expense, an appeal to the public for financial assistance has been made. The use of barges as a means of transport for wounded, and as actual hospitals, has been recently tried by Mr. Hall on the Seine, and has met the complete satisfaction of the French authorities and the great gratitude of the wounded for the tranquillity of this means of transport. The unit of four barges asked for in the first instance will be under the direction and control of the Royal Army Medical Corps, which will supply the army surgeons, nurses, and orderlies, and provide a complete floating hospital for 200 wounded

THE BOMBARDMENT OF THE EAST COAST

The figures of the casualties from the bombardment by German ships of the towns on the East Coast now reach 122 killed and 549 wounded.

DEATH OF AN EMINENT BELGIAN NEUROLOGIST IN ENGLAND

The universities of Oxford and Cambridge have freely given hospitality to the refugee Belgian professors and students. Among the former was the distinguished neurologist, Professor van Gehuchten of Louvain, who went to Cambridge, where he died. His work on the anatomy of the nervous system, on staining methods and chromatolysis, and on the olfactory and acoustic nerve tracts, is well known. He was a great clinician and teacher as well as a great investigator.

The Dangers of the Operator: Death of an Eminent Surgeon from Acute Septicemia

Mr. C. B. Lockwood, one of the most distinguished surgeons of the day, contracted acute septicemia after operating on a patient for appendicular peritonitis. The patient was in a grave condition and speed was necessary. Mr. Lockwood pricked his finger when inserting almost the last stitch. He was taken ill the same night and died five weeks later from septicemia. He was surgeon to St. Bartholomew's Hospital, and well known by his writings on aseptic surgery, hernia, varicocele, cancer of the breast, and most of all by his book on appendicitis, which has been described as the ablest exposition of the subject in English. He was not only a great surgeon, but also a master of terse and epigrammatic style. As an example may be taken his expression, "The man who does not pass flatus dies." It is one of the ironies of fate that a few years ago he read at one of the societies a paper on the unusual subject of the dangers to the operator.

PARIS LETTER

Paris, Dec. 17, 1914.

The War

NERVOUS TROUBLES AMONG WOUNDED SOLDIERS

My army service has permitted me to visit some of the military hospitals and also to examine a considerable number of convalescents after removal to their regimental stations. An especially striking feature is the frequency of nervous troubles, due most frequently to lesions of the nervous centers or of the peripheral nerve but sometimes of psychic origin. In view of the frequency of these complications, it has been decided to form special services under specialists in nervous diseases.

Dr. Paul Sollier of Boulogne-sur-Seine, who has just read a paper before the Académie de médecine on functional paralysis in wounded soldiers, distinguishes four varieties of these paralyses: (1) in emotional subjects, paralysis due to apprehension of the pain caused by moving limbs long kept in an unnatural attitude by apparatus or because of fibromuscular retractions; (2) paralysis due to mental representation (*a*) of movements with loss of the muscular sense and (*b*) of attitudes caused by prolonged disuse of the limbs; (3) paralysis due to a fixed idea of incurability, and (4) paralysis due to hysteric contracture.

Wounds of the nerves of the limbs due to bullets or fragments of shells are frequent, the arms being affected as often as the legs. According to Dr. Henri Claude, who read a paper on this subject before the Société médicale des hôpitaux de Paris, these wounds manifest themselves especially by motor paralyses. The painful forms are rare. Anesthesias are exceptional and particularly characteristic of complete sections of the nerve. What is most frequently observed, even in apparently benign wounds in which the ball merely passes under the skin and heals after a very short period of suppuration, is the sheathing of the nerve in a growth of fibrous tissue which constantly compresses it more closely. The proliferation of this sclerotic tissue causes late paralyses even in cases in which the projectile does not touch the nerve. In such cases operation to liberate the nerve and to surround it with healthy tissue should be performed almost always as soon as suppuration and acute inflammatory reaction have ceased. Mechanotherapy and electrotherapy are indispensable adjuncts of the surgical cure of such cases. From the diagnostic point of view, it is interesting to note that the abolition of the Achilles tendon reflex and of the knee-jerk are early and trustworthy signs of lesions of the sciatic and crural nerves. Investigation of these reflexes is especially useful in subjects inclined to simulation or exaggeration.

Dr. Mauclaire has reported to the Société de chirurgie several cases of motor troubles of psychic origin, taking the form either of paralysis or of contracture, in wounded soldiers whose nervous system had been greatly shaken.

WOUNDS IN BATTLE

Dr. Hartmann of the Faculté de médecine de Paris, who has recently had occasion to observe thousands and to treat hundreds of wounded soldiers, has recently summed up the results of his experience before the Académie de médecine. Of the total number of wounds, those due to artillery projectiles (balls, fragments of shells and of shrapnel) form a large proportion. Out of 268 cases in which the origin of the wound could be determined, 169 were caused by artillery projectiles and 99 by bullets. The frequency of fractures was great—112 cases of fracture out of 311 wounds. In general, these fractures are distinguished from those seen in civil practice by the presence of numerous fragments of bone, by the slight tendency to displacement and by the fact that in limbs with two bones, the lesion is generally limited to one bone. To avoid tetanus, Hartmann recommends that, without regard to the distinction between soiled wounds with fracture and those without fracture or soiling, preventive injection of anti-tetanus serum be practiced in all wounded as soon as possible. To prevent gaseous gangrene the interstitial injections of hydrogen peroxid recommended by Delorme (The Journal, Oct. 24, 1914, p. 1492) appear insufficient to Hartmann, who recommends liberal opening up of the wound and amputation if the limb is swollen throughout its thickness. In the prevention of gaseous gangrene it is important to remember that this complication never develops in wounds which are well opened up even when they are large. It occurs, on the other hand, in cases of small tortuous wounds deep in the tissues. Treatment, therefore, should consist of opening up the course of the projectile, removing all foreign bodies, draining from end to end, and irrigating with hydrogen peroxid.

At one of the last sessions of the Société de médecine de Paris, Dr. Maurice Cazin reported some interesting statistics comparing the results of early with late hospital treatment. In a group of 158 wounded men received at the hospital less than forty-eight hours after battle, all were cured, in spite of the serious character of many of the wounds. Among the wounded received in hospitals after four or five days of transportation in sanitary trains, on the other hand, the mortality in some hospitals reached 10 or 20 per cent. owing to infectious complications (gangrene and tetanus) which might have been avoided by suitable treatment if the patient had been placed in a hospital early. The objection to early hospital treatment of all wounded soldiers, even those not seriously injured, seems to be the fear of encumbering the hospitals near the battlefield. This might be avoided by selecting twice a week, or even daily, the patients who, after several days under observation with rest and hospital hygiene and care, are now fit to be removed. Thus men who are on the way to certain recovery and not, as at present, men whose condition is precarious would be removed by hundreds in the trains of evacuation.

EMETIN IN THE TREATMENT OF TRAUMATIC HEMOPTYSIS

In view of the antihemorrhagic properties of emetin in tuberculous hemoptysis, Drs. J. Dupont and J. Troisier decided to try this remedy in traumatic hemoptysis. In three patients with penetrating bullet wounds of the thorax, they gave subcutaneous injections of emetin hydrochlorid, the dose being 40 mg. The hemoptysis was arrested after one or two injections. Of course, emetin injections could not arrest severe vascular hemorrhages but the pulmonary hemorrhages of men who are capable of being transported appear amenable to this simple treatment. If necessary, the dose may be increased to 80 mg.

HOME COMFORTS FOR THE WOUNDED

The Foyer du Blessé has been founded under the patronage of the Assistance publique. The purpose is to bring to wounded soldiers in the hospitals of Paris all possible material comfort and mental consolation and distraction. The director of the Assistance publique has therefore granted the use of a hall in every hospital where this is possible. This hall will be furnished especially for the use of the wounded, who will find there games, books, periodicals, hot drinks, tobacco, letter-paper, a meeting-place and friends who will endeavor to take the place of the absent family and to render the patients all possible service. Two such halls have been in use from the beginning of the war at the Saint Antoine Hospital, and two new ones have just been inaugurated at the Lariboisière.

Deaths in the Profession

Dr. Léon Lereboullet, medical journalist, has just died. He was born in 1842 at Strasburg, where his father held the chair of zoology and comparative anatomy at the Faculté des sciences of that city. In 1873 he was appointed agrégé professor of clinical medicine at the Ecole d' application de médecine et de pharmacie militaires du Val-de-Grâce. In 1881, after publishing a series of articles on the health service of Tunis which attracted much attention, he secured from Jules Ferry, then prime minister, an investigation which finally brought about the autonomy of the health service in the army. Lereboullet was a collaborator of Dechambre from 1872 and finally succeeded him in the editorship of the Gazette hebdomadaire de médecine and of the Dictionnaire encyclopédique des sciences médicales in 100 volumes. Besides the numerous articles on the practice of medicine, on hygiene and ethics, that he published in these two collections, Lereboullet was the author, in collaboration with Mathias Duval, of a manual of microscopy applied to diagnosis and, in collaboration with Dechambre, of a handy dictionary of medical sciences. In 1890 Lereboullet was elected associate member of the Académie de médecine.

Dr. Charles Périer, president of the Académie de médecine, has just died suddenly, aged 78. His health appeared very robust and nothing foreshadowed his approaching death. He presided over the last sessions of the academy and took part in the discussions during the annual public session. He was elected a member of the academy in 1890 in the section of surgical pathology.

Method for Determining the Presence of the Bacillus Typhosus

At one of the last sessions of the Académie des sciences, Drs. Carnot and Weill-Hallé outlined a practical method for discovering the presence of the bacillus of Eberth in typhoid patients and carriers. Instead of looking for the germ as usual in the feces of the patients, Carnot and Weill-Hallé examine the bile, which is known to be an excellent culture medium for this bacillus. The subject to be examined takes 150 c.c. of olive-oil. An hour later the stomach is catheterized, furnishing a mixture of oil, bile and gastric mucus. After separation of the three substances, the bile is examined for the bacillus; often after passage through the incubator it furnishes a pure culture. The Einhorn tube may be used. After it has penetrated into the pylorus, an aspiration by means of a syringe adapted to the tube will remove the bile pure or mixed with pancreatic juice. This procedure furnishes an easy method of establishing the presence of the bacillus during the whole course of the disease and the convalescence. Carnot and Weill-Hallé have found it up to the eighty-sixth day after complete recovery.

BERLIN LETTER

Berlin, Dec. 8, 1914.

The War

WARM UNDERCLOTHING FOR THE SOLDIERS

It goes without saying that, as in all previous wars, the care of the authorities for the sanitary condition of the army has been considerably aided by private generosity. Up to the present the Red Cross has expended about $1,375,000 (5½ million marks) for these purposes, of which more than $500,000 (2 million marks) were given for clothing and equipment of those serving in the army as well as for their instruction and training, about $225,000 (900,000 marks) for the making of woolen goods and other presents, $175,000 (700,000 marks) for hospital trains, and $150,000 for the care of the relatives of soldiers who are at the front. But these efforts of the Red Cross are greatly exceeded by those which have been put forth by various societies and well-to-do citizens. As an example may be mentioned the fact that the "military committee for warm underclothing," formed at the suggestion of the empress, has already sent to the army woolen goods to the value of $3,750,000 (15 million marks). On a certain day of the week special "wool trains" are run regularly to the armies both of the West and of the East. The cargo of these trains frequently reaches a value of $500,000 (2 million marks). Lately wool blankets have been furnished for the troops, who must often lie all day in the firing trenches. From these facts it is quite evident that in many parts of the army a certain oversupply of woolen material has accumulated. Thus in a medical weekly, a staff surgeon confirms the fact that many soldiers suffer from an oversupply of underclothing. There was found, for instance, on a certain artilleryman the following "epithelium": An overcoat, an army coat, a drilling jacket, a woolen vest, two woolen shirts and one linen shirt. As these goods cannot be carried on the wagons, the troops help themselves by carrying along all the pieces of clothing that have been distributed to them. Naturally, a very systematic distribution of the clothing cannot be carried out.

USE OF ALCOHOL IN THE ARMY

In addition to pieces of clothing, the most various articles of equipment have been supplied to the soldiers for their physical comfort. Among these things, alcohol played a rôle for a certain time, although the use of alcohol in the army has been restricted to the minimum by orders of our military medical service. The autumn storms with their cold winds and frequent rainfall aroused the need for warming drinks among the soldiers; therefore alcoholics were furnished to the privates through the express wishes of some of the commanding generals. But immediately warning voices were raised, especially of physicians, who pointed out the objectionable character of the expense for alcohol. By this means a diminution of these presents has been secured. Also some of the leaders of the troops have pointed out in their published reports that the people might well send other articles or gifts rather than alcoholics. Of some aid in this matter is the fact that in the West the cold is very slight. A well-known clinician, who has been spending some time as a consulting internist in the army of the West, and has returned for a few days, has stated that at present there prevail in the West climatic conditions something like those of the Isle of Wight, so that the need for artificial heat, external or internal, is very slight. In the east, naturally, the condition is quite different.

HEALTH OF THE TROOPS

The mild weather has also had a favorable influence on the health of the troops. The number of diseases due to taking cold has been materially reduced in the West, and especially those affecting the intestinal canal. Frostbites are seldom observed. Even typhoid is restrained within moderate limits, and so far has reached only a fraction of the 75,000 cases which appeared in the war of 1870-1871 in a small force, compared with our present army of millions. Even among physicians, typhoid has already demanded some victims. Altogether in the regular lists of losses published, 350 physicians, that is, about 3 per cent., are included, among them, 112 with slight and 40 with serious wounds; 1 is sick, 65 are dead and 124 missing, of whom the majority are prisoners. The latter, it is to be hoped, will gradually return to their mother country in the way of exchange. A few days ago eight French army surgeons and 85 members of the sanitary corps were discharged from the German prison, and as many of the medical division of our army will return to us from France.

ABUNDANCE OF SUPPLIES AND MONEY

In spite of the enormous numbers, no difficulty has so far been experienced with reference to bandages and medical supplies for the treatment of the wounded. Both in the matter of food and also in that of medicine, our land produces more than it needs. To be sure, the export of a number of medicaments has been forbidden, including antifebrin, aspirin, cocain, formaldehyd, phenol (carbolic acid), morphin, opium, phenacetin, codein, pyramidon, antipyrin, salipyrin, mercury and mercuric salts, bacterial serums and the like.

HELP FOR LYING-IN WOMEN

The imperial fund affords an extraordinary contribution to lying-in women for the period after delivery, provided their husbands are serving in the army or medical corps or similar service not of a commercial nature during the present war, and that these men are insured against sickness. The assistance consists in all those services which the imperial insurance law designates as *Wochenhilfe*, and includes what the Krankenkassen are legally obliged to furnish and also in general what they are able to undertake as a voluntary contribution through their fees. These services include the help of a midwife or a physician not only during labor, but also for any complaints due to pregnancy, and further a stipend for the puerperium and for nursing. The puerperal stipend is paid at the rate of a mark (24 cents) a day for eight weeks. The nursing money is received at the rate of 50 pfennig (12 cents) per day by the mothers, as long as they themselves nurse their infants, for a period of twelve weeks after the delivery. The Krankenkassen furnish these services and receive compensation for them from the imperial treasury. For the treatment during labor, 25 marks are paid for each case, and an amount up to 10 marks for illness during pregnancy. The insurance societies may choose to furnish treatment by a physician or midwife directly instead of providing a cash payment. This is on condition that the insurance society has a contract for this purpose with its physician and could not, for this reason, as well as on account of the necessity of using the imperial assistance generally in an even manner, make general rules. It is important that the help in case of labor shall also be assured in cases in which the husband, by entering the army, has made no use of his right for voluntary additional insurance. Moreover, the Krankenkassen must supply the same assistance in case of labor for women who have insured themselves and in whose case there is no question of the husband taking part in the war.

THE UNEMPLOYED

As far as the assistance to the unemployed is concerned, it must be stated that the number of these persons has been continually decreasing for some weeks. The entire number of members liable to insurance of the twenty-eight local general sickness insurance societies of Berlin increased in one week by 2,000, or 0.5 per cent. The 210 trade Krankenkassen showed an increase of 0.9 per cent.. Among the free companies, the number of unemployed has fallen 6.5 per cent. in one week.

TREATMENT OF THE WOUNDED

The results of the treatment of the wounded are, as previously, particularly favorable. Only tetanus and the gas phlegmons have been observed among wound infections with an apparently greater frequency in this war. The percentage of these complications is in general, however, small. So far as can be judged at present, the number of those who have become fit for service again is considerable. According to a statement by Czerny of Heidelberg, 37.5 per cent. of the wounded in his experience are already cured, and only 6.5 per cent. have remained unfit for duty.

Seventieth Birthday of Professor Fritsch

Professor Fritsch, formerly for many years director of the Bonn University clinic for gynecology, celebrated his seventieth birthday, December 5. He was first assistant of Professor Olshausen, joined the faculty of Halle in 1874 as privat-docent, in 1882 became regular professor and the successor of Spiegelberg at Breslau, and in 1883 director of the gynecologic clinic of Bonn. In 1911, he retired from his position on account of ill health, and removed to Hamburg, principally in order to be treated by his son-in-law, Professor Brauer. Of his text-books, "Das Lehrbuch über Frauenkrankheiten," "Das Lehrbuch der Geburtshilfe," "Die gerichtsärztliche Geburtshilfe," and "Pathologie und Therapie des Wochenbetts" are noteworthy.

Marriages

Delivan Alexander MacGregor, M.D., Wheeling, W. Va., to Miss Ethel Marguerite Eastman of Iowa City, Ia., December 31.

Walter Wynn Barnett, M.D., Fort Wayne, Ind., to Miss Irma Bogash of Valparaiso, Ind., December 23.

John Walter Morris, M.D., to Miss Frances J. Moorman, both of Somerville, Tenn., December 29.

Henry Shillingford Miles, M.D., to Miss Edith Alicia Zink, both of Bridgeport, Conn., January 2.

John Luther Spangler, M.D., York, Pa., to Miss Mary E. Fink of Manchester Borough, Pa., December 25.

Philip Mills Jones, M.D., to Miss Helen Louise Spalding, both of San Francisco, December 13.

Charles Shivers Heritage, M.D., to Miss Annie Whitney Knock, both of Glassboro, N. J., November 11.

Deaths

Dudley Peter Allen, M.D. Harvard Medical School, 1880; a Fellow of the American Medical Association and formerly president of the Ohio State Medical Association; president of the American Surgical Association in 1906-1907; professor of principles of surgery in the Medical Department of Medical Reserve University, Cleveland, for many years, and later emeritus professor of surgery; visiting surgeon to the Lakeside Hospital and consulting surgeon to the Charity and City hospitals, Cleveland; a director of the First National Bank and Trust Company, Cleveland, and a trustee of Oberlin College which conferred on him the honorary degrees of M.A. in 1883 and of LL.D. in 1908; died in a hotel in New York City, January 6, from pneumonia, aged 62.

Waldemar Edward Fischer, M.D. Marion-Sims College of Medicine, St. Louis, 1888; a Fellow of the American Medical Association; formerly assistant to the eye clinic in his Alma Mater; oculist to the Missouri Baptist Sanitarium, St. Louis; First Lieutenant Medical Reserve Corps, U. S. Army; a well-known ophthalmologist of St. Louis; died in that city, December 9, it is believed by his own hand, while mentally irresponsible.

David J. Loring, M.D. Rush Medical College, 1878; a Fellow of the American Medical Association; and secretary to the Porter County (Ind.) Medical Society; surgeon to the Loring Private Hospital, Valparaiso; local surgeon of the Pennsylvania, Grand Trunk and Nickel Plate systems; formerly surgeon in chief to St. Margaret's Hospital, Hammond; died at his home in Valparaiso, Ind., December 29, from ptomain poisoning, aged 66.

Henry B. A. Kugeler, M.D. University of California, San Francisco, 1890; a Fellow of the American Medical Association; instructor in operative surgery and chief of the surgical dispensary clinic in his Alma Mater; visiting surgeon to St. Joseph's Hospital, San Francisco; a well-known and highly respected surgeon of San Francisco; long a sufferer from kidney disease; died December 27, from carcinoma of the prostate gland, aged 44.

James B. Cox, M.D. College of Physicians and Surgeons, Keokuk, 1865; a pioneer practitioner of Benton County, Ia., and for nearly half a century a practitioner of Belle Plaine; and for thirty years local surgeon to the Northwestern System; died suddenly at his home in Belle Plaine, December 20, aged 72.

Zachariah Ford Lillard, M.D. Missouri Medical College, St. Louis, 1891; a member of the State Medical Association of Texas; local surgeon at Houston for the Southern Pacific System; and a member of the Houston Board of Health; died in the John Sealy Hospital, Galveston, Tex., December 27, aged 54.

Alton H. Garratt, M.D. Trinity Medical College, Toronto, 1888; demonstrator of clinical gynecology in the University of Toronto; one of the founders of the Toronto General and St. Michael's hospitals, Toronto; died at his home in that city, December 21, from heart disease, aged 49.

Elijah B. Bush, M.D. Atlanta (Ga.) Medical College, 1850; formerly a member of the general assembly and senate of

Georgia, and for several years physician in chief to the state penitentiary; died at his home in Colquitt, Ga., December 22, from nephritis, aged 54.

Charles L. Grube, M.D. Saginaw Valley Medical College, Saginaw, Mich., 1900; a physician and druggist of Saginaw, Mich.; once coroner of Saginaw County and for two terms city physician of Saginaw; died in the Pontiac State Hospital, December 21, aged 40.

John Harry Swaving, M.D. University of Pennsylvania, Philadelphia, 1889; formerly a Fellow of the American Medical Association; surgeon to the State Sanatorium, Hamburg; died at his home in Pottsville, Pa., December 30, from cerebral hemorrhage, aged 47.

Eber Leslie Washburn, M.D. University of Vermont, Burlington, 1896; a Fellow of the American Medical Association and a specialist on diseases of the eye, ear, nose and throat of East Berkshire, Vt.; was found dead in his barn, December 14, aged 50.

John H. Dupin (license, Kentucky, forty years practice, 1893) a veteran of the Mexican War and for many years a practitioner and dentist of Uniontown, Ky.; died at the home of his daughter in St. Louis, in September, from senile debility, aged 87.

Calvin Brewer Anderson, M.D. Dartmouth Medical School, Hanover, N. H., 1878; a veteran of the Civil War and for many years a practitioner of Vermont; died at the home of his daughter in San Antonio, Tex., August 30, from kidney disease, aged 78.

Robert C. Grigg, M.D. Rush Medical College, 1871; a veteran of the Civil War; for thirty-two years a practitioner of Murray, Ia., and later a resident of Des Moines and Sioux City; died at his home in the latter city, December 12, aged 76.

William Marcellus Eddy, M.D. Cleveland University of Medicine and Surgery, 1865; later instructor in anatomy in his Alma Mater; a pioneer practitioner of Marengo, Ia.; died at his home in that place, December 27, aged 76.

Henry Dusenbury, M.D. College of Physicians and Surgeons in the City of New York, 1866; for nearly half a century a practitioner of Williamsburg, Brooklyn; died at his home, December 30, from senile debility, aged 80.

John T. Johnson, M.D. University of Pennsylvania, Philadelphia, 1861; a Confederate veteran and for nearly half a century a practitioner of Hickory, N. C.; died at his home in that place, December 24, from pneumonia, aged 78.

James Vercoe, M.D. Michigan College of Medicine, Detroit, 1881; for thirty years a physician and druggist of Skagit County, Wash.; died on his ranch on the Olympia Marsh, near Maiben Station, Wash., December 19.

George Loring Pierce, M.D. Medical School of Maine, Brunswick, 1861; Jefferson Medical College, 1879; for many years a practitioner of New York City; died at his old home in Kittery Depot, Me., December 22, aged 77.

Junius Terry, M.D. Missouri Medical College, St. Louis, 1861; for thirty years a resident of Chicago; died at his home in that city, December 28, aged 73.

John Edgar Tamlyn, M.D. University of Toronto, Ont., 1864; for forty-eight years a practitioner of Wingham, Ont.; died at his home December 18, aged 81.

Thomas J. Rude (license, Kansas, 1903), formerly principal of the Burton (Kan.) schools; died at his home in Cambridge, Kan., December 13, aged 58.

Sherwood E. Seeley (license, Illinois, years of practice, 1877), for half a century a resident of Fulton, Ill.; died at his home, December 18, aged 82.

George Nichols, M.D. Hahnemann Medical College, Philadelphia, 1861; died at his home in Brooklyn, December 10, from heart disease, aged 85.

Robert C. Carroll, M.D. Western University, London, Ont., 1909; of Calgary, Alta.; died at North Dunwich, Ont., about November 23, aged 31.

Walter W. Atkins, M.D. College of Physicians and Surgeons, Keokuk, Ia., 1887; died at his home in Milton, Ia., December 14, aged 61.

Morton Grant Sturdevant, M.D. University of Louisville, Ky., 1896; died recently at his home in Salem, Ind., aged 43.

Frank A. Barber, M.D. Bennett Medical College, Chicago, 1878; died at his home in Chicago, December 27, aged 60.

Julius L. Friedler, M.D. Bellevue Hospital Medical College, 1890; died at his home in New York City, December 13, aged 59.

ABOLISHING SECRECY AND MYSTERY IN PATENT MEDICINES

New York City Makes a Move to Protect the Public Against the Nostrum Evil

[For some time past, Dr. S. S. Goldwater, Health Commissioner of New York City, has been making an effort to protect the public against the dangers and frauds in "patent medicines." Dr. Goldwater's work was finally crystalized into a revision of the sanitary code that was adopted by the New York Board of Health at its regular meeting Dec. 31, 1914. That part of the revised code regulating the sale of proprietary medicines requires that all "patent medicines" shall bear on the labels the names of their ingredients or, as an alternative, the names of such ingredients shall be registered with the Department of Health. This regulation is not to go into effect before Dec. 31, 1915, thus allowing druggists a year to dispose of stock already on hand. Needless to say, the "patent medicine" interests are up in arms against this attempt to destroy their most valuable assets—secrecy and mystery.

The New York *Tribune* is printing a series of articles on advertising, written from the standpoint of the public rather than the advertiser. The series is written by Samuel Hopkins Adams, whose name is a sufficient guarantee that the subject is being dealt with, not only from the view of the best interests of the public, but also in a way that admits of no equivocation. The first article of the series appeared in the *Tribune* of January 4. In the *Tribune* January 8, Mr. Adams describes the protest made at the public hearing held in the City Hall on January 7 by the "patent medicine" interests against the Board of Health's new labeling regulation. We give below in full Mr. Adams' article. Our readers will recognize some familiar names in those who appeared before the Board of Health in behalf of "patent medicines." The name of Dr. William C. Anderson will call to the memory of our readers The Journal's exposés of the "American Druggists Syndicate," an organization that brazenly announced that it had appropriated physicians' prescriptions and was dispensing them in ready-made packages. Dr. Anderson was chairman of the syndicate's "formula committee" which was alleged to pass on the value of "thousands of prescriptions written by the most successful physicians in every state in the Union" and to "select the premium prescription and offer it to the public in a ready-made package."

Henry R. Strong, who went from St. Louis to New York to join in the protests is the publisher of the *Medical Brief* and the *National Druggist*. The *Medical Brief* is, as most physicians know, a nostrum-exploiting sheet, whose continued existence is due to the easy tolerance of the medical profession. The *National Druggist* has for years apparently acted as the mouthpiece for the "patent medicine" interests. Letters and pamphlets have been circulated broadcast, blackguarding the medical profession in general and the American Medical Association in particular. "The Menace of the Dispensing Doctor," "A Conspiracy to Establish a Physicians' Trust," "The Machinations of the American Medical Association" and "Confiscatory Legislation"—these are but a few of the tirades from the *National Druggist* against the medical profession. It was the *National Drug-*

gist also that protested against any amendment to the Food and Drugs Act, that would prohibit false and fraudulent claims for curative effects of "patent medicines." Broadly, it may be said that the *Medical Brief* and the *National Druggist* stand for everything that reputable physicians oppose. It is not surprising, therefore, that Mr. Strong was on hand to champion the interests of his clientele at the public hearing for the New York Board of Health.

It was, of course, entirely fitting that A. V. Payne, exploiter of as cruel a fraud as there is on the market—Pulmonol, an alleged "consumption cure"—should join hands with Mr. Strong, Dr. Anderson, Mr. Thompson, the general counsel for the "patent medicine" combine, and Albert Plaut, president of Lehn and Fink. But we will give Mr. Adams' report in full, as it appeared in the *Tribune*, and our readers can draw their own conclusions:]

CONSPIRACY, BOGIE CRY OF MEDICINE MEN

INTERESTS BACK OF TRAFFIC IN PATENT "CURES" PROTEST AT CITY HALL

By Samuel Hopkins Adams

All the familiar patent medicine bogies were trotted out into the light of day at the Board of Health hearing held in the City Hall yesterday afternoon and made to rattle their poor, ricketty bones in protest against the board's honest labelling regulation. This order requires that the ingredients of every patent medicine sold in this city shall either be stated on the label or filed with the board. Secrecy being the life of trade with the nostrums, the representatives of various allied industries, retail and wholesale druggists, patent medicine manufacturers, handlers of crooked advertising, proprietors of not-too-particular journals, lawyers and quacks flocked to the place in such numbers that the big room couldn't hold all of them.

They shouted approval when their spokesman denounced the wicked "medical trust" which is trying to keep the beneficent dopes and booze medicines from doing so much good in secret; they wildly cheered the quack doctor who seized the occasion to give a little advertising to his own fake consumption cure; and they hissed, booed and hooted the presiding officer, Dr. Goldwater, when he attempted to stem the tide of general denunciation and get down to specific data.

QUACKS HAVE A DAY

It was distinctly and exclusively their day. Only opposition to the measure was in order, the only restriction being that legal points were not permitted. The forces of secrecy in medicine were marshalled by Dr. William C. Anderson, who, to do him justice, did his best against heavy odds to keep his unruly followers in order. He opened the meeting for the opponents of the bill by stating his imperishable conviction that there were already all the patent medicine laws on the books that the public could stand, to which sentiment the embattled druggists on the benches responded with howls of approbation. He then introduced Albert Plaut, of Lehn & Fink, a wholesale drug firm.

Mr. Plaut was a perfect Cassandra of calamity. If the Board of Health regulation was enforced, he declared, eight out of the twelve great drug houses in the city would have to move to Jersey or elsewhere. Dr. Goldwater, whose disposition to get at the bottom of matters proved embarassing if not actually painful to various of the speakers in the course of the proceedings, asked why the other four should stay. After some hesitancy Mr. Plaut decided that it would be because their trade was largely local. There was no other form of business, he declared, more open and above-board than the business of selling drugs.

"If that is the case," queried the commissioner, "why do you insist on secrecy?"

To which the speaker hadn't found a reply at time of going to press.

HOOT AT GOLDWATER

Dr. J. H. Rehfuss, of the New York Pharmaceutical Association, roused the interest of the board to such an extent that they asked him several questions pertinent to the line of his remarks. This was hotly resented by the embattled druggists, who yelled, hooted, hissed and warned Dr. Goldwater that he was in the United States, where he "couldn't put any Russian business over."

When the disorder was quieted, Mr. Henry R. Strong, representing the pharmaceutical press, took the floor to enunciate the noble principle, with much gesticulatory emphasis, that he was of Anglo-Saxon blood and nobody could take away from him the right to drink what he wished. Nobody being found who wanted to, he made a somewhat mixed impression upon his hearers by telling them that he knew the drug trade well, and that he didn't doubt but what a large proportion of those present were unprincipled. To conclude, he produced the old bogie of "medical trust conspiracy." One interesting point which he neglected to mention was that that portion of the pharmaceutical press which he represents lives largely on fraudulent medical advertisements which a high class drug medium, like the Druggists' Circular, for example, would not permit in its columns.

The singular spectacle of an official intrusted with the safeguarding of the public health acting directly against the interests of the public health was presented when Alderman Jacob Weil took the floor to oppose the bill. In private life Mr. Weil is a jobber in the drug trade. In public life he is chairman of the health committee of the Board of Aldermen. His proposition, which had at least the virtue of ingenuousness, was that the whole matter be referred to his committee. Presumably on the ground that he wasn't sure whether Mr. Weil would act upon it as an alderman or as a secrecy-defending druggist, Dr. Goldwater failed to seize this opportunity of ending the trouble. Unfortunately the aldermanic advocate fell into a snare when he declared that all good and high-minded druggists, the kind whom he saw before him in such impressive numbers, were against the evil patent medicines and would support an ordinance, for example, forbidding the sale of consumption cures.

"MEDICAL TRUST" NEW BOGIE

Straightway up jumped Dr. A. V. Payne, of Pulmonol ill-fame. He sailed into the "medical trust"; he denounced the American Medical Association; he fulminated against conspiracy, and he was fairly launched upon a glowing testimonial to his own fake consumption cure when the chair called him to order. And that great crowd of good and high minded druggists (Alderman Weil's guarantee), strong against the evil patent medicines, cheered the exponent of the wickedest and meanest of all forms of charlatanry to the echo. Mr. Weil was not called in rebuttal. After Samuel C. Henry had spoken for the out-of-town drug trade a gentleman named Weinert appeared as representing the poor. The bill, he said, would be very bad for the poor. If secrecy were abolished on the patent medicine bottle the submerged tenth of our populace, if Mr. Weinert is to be believed, would wither away and perish, presumably of chagrin at finding out what sort of trash they had been paying good money for all these years—though the speaker didn't say so. Mild but insistent questioning by Dr. Goldwater elicited the fact from the reluctant lips of Weinert that he was an advertising solicitor for two East Side papers which subsist largely on patent medicine advertising. After this Mr. Weinert seemed to lose interest in himself.

Another coy speaker was Henry B. Thompson. Bland and oratorical is Mr. Thompson, as befits the general counsel for the Proprietary Association of America, better known as the patent medicine combination; and quite outspoken to the extent of explaining his official status. The coyness developed when he was asked for details.

"What is the Proprietary Association?" asked Dr. Goldwater.

"An organization of manufacturers of proprietary remedies," was the reply.

"Will you give a list of membership?"

"I will not," said Mr. Thompson shrinkingly, but with determination.

"Just one or two?" persuaded the commissioner.

Mr. Thompson, after a struggle with his natural reticence, managed to emit the style and title of a comparatively innocent liver pill.

"Another?" suggested the presiding official.

Further painful effort produced the name of a laxative syrup.

"More?" encouraged Dr. Goldwater.

At this point aphasia supervened. In vain did Mr. Thompson call upon his memory. All the great, blatant quackeries which club together to employ him had slipped from his mind, though their advertisements afflict the eye daily from coast to coast. He shyly murmured something about "a good many others," and launched into forensic oratory to prove that the board had no power to limit personal liberty, confiscate property rights, interfere with business, and so on.

Then Peter Diamond, a type of the oldtime high-class prescription druggist, made a temperate speech, objecting to the regulation as infringing upon the practice of pharmacy. Professor Raubenheimer dipped into patent medicine history, and the hearing closed.

BELL-ANS (PA-PAY-ANS, BELL)

Another "Patent Medicine" Foisted on the Public Through the Medical Profession

With such nostrums as Antikamnia and Resinol fresh in mind as flagrant examples of "patent medicines" introduced to the public through the medical profession, what follows regarding Bell-ans, or, as it is better remembered by physicians, Pa-pay-ans (Bell), will take on an added interest. Briefly, Bell-ans is the new name of a tablet that, according to chemists' reports, is essentially charcoal, baking soda and ginger, flavored with oil of wintergreen. Its selling point, in the past at least, has been the alleged presence of papain. This drug, Bell & Co. allege, is present in their tablets and they claim is "the digestive principle obtained by our own exclusive process from the fruit of *Carica papaya.*" As long ago as 1909, the Council on Pharmacy and Chemistry attempted to find papain present in what was then called Pap-pay-ans (Bell) and to determine the digestive power of the tablets but with negative results. The efforts of other chemists were equally unavailing.

In January, 1914, Bell and Company changed the name of the product "Pa-pay-ans (Bell)" to "Bell-ans." As The Journal remarked soon after, it seemed probable that, as the name of a nostrum of this kind is the manufacturer's most valuable asset, the name was hardly changed, as was alleged, for purely euphonious reasons. It seemed more likely that as analyses had indicated there was not, and probably never had been, any appreciable amount of papain in the product, the change of name might be due to the fear that some day the misleading name might bring the preparation in conflict with the federal Food and Drugs Act.

For years physicians have realized that the methods of exploitation of Pa-pay-ans (Bell) have been such as to make the medical profession a vast free advertising agency for the nostrum. So far as we know Pa-pay-ans (Bell) has never been advertised in lay journals—newspapers, etc. Certain medical journals, however, have, for a long time, carried the advertisements of Pa-pay-ans (Bell)—and later of Bell-ans—while Bell & Co. has been lavish in its distribution of free samples, blotters and other advertising paraphernalia direct to the medical profession.

Now it seems, Bell and Company are going direct to the public by means of vest-pocket samples and letters. The letter, a miniature facsimile of which we reproduce, is one addressed to laymen and accompanies a vest-pocket box of the nostrum.

Here are some of the things that Bell and Company claim Bell-ans will do:

> "It removes flatulence, vertigo, weakness and other symptoms of indigestion quickly and pleasantly."
>
> "It relieves vomiting in pregnancy, alcoholism, seasickness and cholera morbus. . . ."
>
> "To promote appetite, digestion, and the elimination of toxic and waste material, prescribe two Bell-ans. . . ."
>
> ". . . prevent eruptions, nausea, vertigo, pain, etc. . . ."
>
> ". . . remove distension, pain, weakness, depression, etc. . . ."
>
> "There is no derangement of the digestive organs upon which the proper dose of Bell-ans (Pa-pay-ans, Bell) will not act quickly, pleasantly and favorably . . ."

Dear Sir:-

Please accept, with our compliments and good wishes, this pocket box of our product BELL-ANS.

We have been making BELL-ANS for nearly twenty years and over one hundred thousand physicians are now prescribing it. It is perfectly harmless, as any druggist will tell you, and it certainly relieves Indigestion and sweetens the breath.

Kindly oblige us by giving BELL-ANS a trial and, if you like, write us of the results.

With kindest regards, we are,
Sincerely yours,
Bell & Co. (Inc.)

Dec. 24th, 1914.

Miniature facsimile of a letter received by a layman. It was accompanied by a small box of Bell-ans. Two points are worth noting: ". . . one hundred thousand physicians are now prescribing it"; "any druggist will tell you" that it is perfectly harmless!

There is no physician living who really believes such claims as these! Yet on the medical profession rests the responsibility for the exploitation of this nostrum. Those medical journals which accept advertisements for things of this kind are not so much to blame as those physicians who unprotestingly tolerate the journals that do so. Privately owned medical journals are published, usually, as a commercial proposition; they reflect, to a greater or lesser extent, the attitude of their readers, subscribers and contributors. There are at least three medical journals which carry the advertisements of Bell-ans. They are the *New York Medical Journal*, the *International Journal of Surgery* and the *Massachusetts Medical Journal.*

Bell-ans (Pa-pay-ans, Bell) possesses the virtues—and they are few—and the limitations—and these are many—inherent to a mixture of bicarbonate of soda, ginger and charcoal. Any druggist could put up just as good a remedy, and any physician could write a prescription for a better one in those cases in which he might think it indicated. The whole secret of the commercial success of Bell-ans lies in the mystery of its composition and the fraudulence of the claims that have been made for it. The same tablets put out under a non-proprietary name, as an open formula and with claims that were reasonable and true, would have had practically no sale. The commercial success of Bell-ans is a monument whose foundation rests equally on the unscrupulousness of the manufacturer and on the gullibility of a learned profession.

Correspondence

"Hospitalism" and Infant Hospitals

To the Editor:—I regret very deeply that Dr. Henry Dwight Chapin did not make two articles out of the one entitled, "Are Institutions for Infants Necessary?" which appeared in The Journal of January 2. One article might then have been entitled, "Are Infant Asylums Necessary?" and his conclusion would have been "No," in agreement with practically all thought on this line of social work.

His second article might have had the title, "How Can Mortality in Infant Hospitals be Reduced?" or "Successful Methods Used in a Certain Infant Hospital, as Shown by Its Low Mortality Record." An abstract of the second article might then have read as follows: "Hospital marasmus the result of bad hygiene and ward infections. Such infections recall mortality of old time maternity hospitals. No excuse for either in this century. Methods which allow such infections have survived from 200 years ago. Modern methods in hygiene, individualization, and aseptic nursing prevent high mortality. Skilled care by trained hospital attendants desirable. Infant hospitals necessary to save infant life, both in acute and chronic ailments. Long residence will not expose infants to cross infection and bad hygiene, if short residence does not. Modern methods in a certain infant hospital are based on principle that infections are carried, not air-borne. Hygienic methods adequate to baby life worked out in detail. Personality and individuality of babies respected, studied and acted on. Result is that mortality is less than that of community in which hospital is located in spite of fact that only sick babies are admitted. Hospitalism not allowed to develop."

Naturally I cannot expect successfully to force my thoughts on another, but am only imagining what Dr. Chapin might have written to please me. Without hint of personal criticism I may be allowed to regret that he has so unfortunately confused the work of infant hospitals and asylums, and has seemed to pass up the problems of infant hospitals as hopeless. To turn all chronic cases of infant sickness over to the substandard care of foster mothers would be to do away with invaluable and efficient hospital methods. We have the knowledge and ability to prevent "hospitalism" in infant hospitals. This knowledge should be applied, as I know from personal experience that it can be.

A. W. Gray, M.D., Milwaukee.

[The above letter was referred to Dr. Henry D. Chapin who replied:]

To the Editor:—I regret that my recent article "Are Institutions for Infants Necessary?" does not seem wholly to have pleased your correspondent. However, I think he has failed to grasp the meaning of my suggestions. I do not believe we differ very much. My contention is that many sick infants may be successfully treated at home if efficient nursing can be obtained. The statistics I produced from the Henry Street Settlement, New York, prove this point, although the work was carried out in the most densely populated tenement house district in the world. I do not propose to hand over sick infants to foster mothers as the doctor seems to imagine, and I tried to make very clear the dstinction between infant asylums and hospitals. The systematized and regulated "boarding out" I advise only as a substitute for the asylums which should all be abolished.

I tried to emphasize the fact that strict aseptic nursing and small units are essential to success. These I have employed, but a very large experience in this work, under favorable conditions, has convinced me that a short stay in the hospital is best for the infant, who should be discharged as soon as the acute symptoms have subsided. The infant seems to lose immunity and resistance after too long a stay in a hospital, even with good nursing and care. As an example, unless all visitors are absolutely barred, influenza and other infections are exceedingly difficult to constantly keep out. The nurses and attendants themselves may at times be the carriers of these infections. My critic seems to have been fortunate in always securing the perfection of nursing so necessary for infants—but, even with this, the baby is usually better at home during the convalescent stage. "The personality and individuality of babies" can here be best conserved. Some infants' hospitals depend largely for their nursing upon women who are under short training to act as nursery maids.

I am familiar with many of the infants' hospitals of the world and willingly concede that under the conditions mentioned in my article they can do good work, but there is no great need for their multiplication. Some of the work that devolves upon them can, with a little extra care, be accomplished as well at home and often under safer and more normal conditions for the infant. The personality of the baby calls for individual and loving care if the best results are to be obtained.

Henry Dwight Chapin, M.D., New York.

Queries and Minor Notes

Anonymous Communications and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

OLIVE AND COTTONSEED OILS

To the Editor:—1. What is the comparative value of olive and cottonseed oils?

2. Are our olive oils, produced here or imported, adulterated with cottonseed *oil?* M. R. Morden, M.D., Adrian, Mich.

Answer.—1. For ordinary pharmaceutical uses, there seems to be no reason why one cannot be substituted for the other. Their dietetic value is also essentially the same.

2. While the exportation of cottonseed oil for the purpose of reimporting it as olive oil or using it to adulterate that oil was formerly quite prevalent, the practice, we understand, has practically ceased.

REQUEST FOR TITLES OF ORIGINAL CONTRIBUTIONS TO THE MEDICAL SCIENCES

To the Editor:—I am writing a paper on the *original* contributions of America to medical sciences.

By *original* contribution is meant something new that has not been done before by somebody else.

I respectfully solicit the members of the profession to send me the titles of their original contributions, and also the titles of the original contributions of other members of the profession, past or present.

Edmond Souchon, 2403 St. Charles Avenue, New Orleans.
Jan. 7, 1915.

REMOVAL OF RUST FROM INSTRUMENTS

To the Editor:—Your correspondent (The Journal, Jan. 2, 1915, p. 72) should try a solution of tin chlorid, preferably hot, into which the rusted instruments are to be laid and afterward *rinsed in* clear water. The abrasives remove the polish.

Edmund D. Spears, M.D., Boston.

Armies of Slaughter and the Army of Prevention.—We shudder at the needless slaughter of the brave young fellows —allies and foes alike—but think of the slaughter which goes on in our homes, just as cruel as, often more cruel than, that of the battle-field! Tuberculosis alone will kill ten times as many this year in Great Britain as will die abroad for their country. Comparing the death-rate in England to-day with that of fifty years ago we may say that, as a result of the work of the other army, more will be saved from death by enteric fever in 1914 than will be killed this year in the war. Eberth's *Bacillus typhosus* will kill in 1914 in the United States more than will German shrapnel and bullets in France and Russia. Moving in silence, the great army of sanitation, with a general staff and leaders of all lands and languages, claims allegiance only to Humanity. In war it has not often fought winning campaigns, but the new knowledge is full of such promise that even the vanquished may be victors.—Sir W. Osler in *British Medical Journal.*

Medical Education and State Boards of Registration

COMING EXAMINATIONS

Iowa: Des Moines, Jan. 19-21, 1915. Sec., Dr. Guilford H. Sumner, Capitol Bldg., Des Moines.

Kansas: Topeka, Feb. 9-11, 1915. Sec., Dr. H. A. Dykes, Lebanon.

New York: Albany, Buffalo, New York, Syracuse, Jan. 26-29, 1915. Mr. H. H. Horner, Chief, Examination Division, State Education Bldg., Albany.

Massachusetts September Report

Dr. Walter P. Bowers, secretary of the Massachusetts State Board of Registration in Medicine, reports the oral, practical and written examination held at Boston, Sept. 8-10, 1914. The total number of subjects examined in was 13; total number of questions asked, 74; percentage required to pass, 75. The total number of candidates examined was 51, of whom 20 passed, including one osteopath, and 31 failed, including 7 osteopaths and 12 non-graduates. The following colleges were represented:

PASSED

College	Year Grad.	Per Cent.
Yale Medical School	(1905)	81.4
Indiana College of Medicine and Midwifery	(1888)	77.7*
Medical School of Maine (1913) 75.7, 80.6;	(1914)	75.6

The following questions were asked:

DIAGNOSIS AND THERAPEUTICS

1. Mention three of the most frequent complications which may arise during an attack of lobar pneumonia. Give treatment for one of them. 2. What complications may arise in whooping-cough? What means should be adopted in the treatment of the disease to prevent them? 3. Define and give etiology of Ludwig's angina (cellulitis of the neck). 4. Give the pathognomonic symptom or symptoms, if such there be, of malaria. Also your treatment for that disease. 5. Write a page on the causes, symptoms and treatment of exophthalmic goiter. 6. Give description, causes and treatment of a case of urticaria. 7. Patient, a man 44 years of age, began a year ago with frequent attacks of vertigo, persistent and increasing headache, difficulty of vision and speech, convulsions without loss of consciousness, and at times nausea and vomiting. What is your diagnosis? 8. Outline a course of treatment for a case of gout. 9. Give causes, symptoms and treatment of herpes zoster. 10. What indications or symptoms would call for the administration of ergot? If your practice does not include the use of drugs, what methods would you employ in place of the drug?

ANATOMY AND HISTOLOGY

1. What anatomic structures are involved in the problem of fallen arches? 2. Describe the semicircular canals. 3. Give an outline of the regional anatomy of the neck. 4. Give a description of heart muscle. 5. Describe the hip joint. 6. What bones are involved in so-called Colles' fracture? 7. Describe the pancreas. 8. Give the distribution and arrangement of the blood-vessels of the kidney. 9. Describe the patella, giving its relations and attachments. 10. What are sesamoid bones and where found?

PEDIATRICS AND TOXICOLOGY

1. What standards should be required of milk producers? 2. Give etiology and treatment of cholera infantum. 3. What would indicate a pyloric stenosis in early life? 4. Give your treatment for chorea. 5. What are the dangers incident to removal of tonsils and adenoids? 6. What are the different forms of congenital herniae; what should be done in each case? 7. What is the cause of hydrocephalus? What treatment would you recommend? 8. Describe a case of toadstool poisoning and give treatment. 9. Differentiate strychnia and belladonna poisoning. 10. Describe clinically and pathologically chronic lead poisoning.

OBSTETRICS AND GYNECOLOGY

1. Why should the blood-pressure be taken during pregnancy? 2. How should a pregnant woman be advised concerning the care of her digestive organs during pregnancy? 3. How would you diagnose a twin pregnancy at the eighth month? 4. Can you always make a differential diagnosis between uterine fibroma and pregnancy? If so, how? 5. If a hand is found presenting during labor, what should be done? 6. What would lead you to suspect a dead fetus in utero at the eighth month? What questions would you ask the parents, and what advice would you give? 7. What is the explanation of pus tubes? Assuming that the patient may not be operated on, what will probably be the future history of such a case? 8. What is the law relating to the care of the eye of a new-born child? 9. Give the etiology and treatment of icterus neonatorum. 10. How do you treat caput succedaneum?

SURGERY

1. A woman 60 years of age, on rising in the morning, finds that her urine is distinctly bloody. She has no pain. What investigations should be made? 2. A patient has a continued fever lasting two weeks, ranging from 99 in the morning to 101.5 at night. She has two to four loose stools daily. The tongue is coated. Her abdomen is slightly tender to pressure to the left of the bladder region, and below the margin of the ribs 1 inch to the right of the right mammary line there is another tender area with slight resistance. Two years ago she had her breast removed for a so-called fibroid tumor. She has a negative Widal. She has a white count of 15,000. What would you do? 3. What are the indications for splenectomy? 4. What would you do for osteomyelitis of the tibia? 5. What is meant by artificial pneumothorax? 6. Discuss the surgical problem of abscess of the lung. 7. Describe briefly a case of abdominal fat necrosis, and state how it should be treated. 8. Give the etiology of cholelithiasis. 9. Under what circumstances may anastomosis of blood-vessels be employed? 10. A patient has round cell sarcoma of the glands of the neck. What may be done, and what is the probable history following treatment?

PATHOLOGY AND BACTERIOLOGY

1. Explain the phenomena of active and passive hyperemia. 2. A patient has an acute septicemia. What changes would be found in parenchymatous organs? 3. A patient dies of pyemia. Describe the kidney in such a case. 4. A person dies of abscess of the liver. Explain what may have caused this condition. 5. What would cause thrombosis of the mesenteric vessels? 6. Give the pathology of the different common forms of cystitis. 7. Give the pathology of elephantiasis. 8. Describe the blood in a case of myelogenous leukemia. 9. Give the pathology of malaria. 10. Describe the hookworm.

PHYSIOLOGY AND HYGIENE

1. What is the function and appearance of lymph? 2. What dietary conditions influence favorably or unfavorably the development of the teeth? 3. Describe and give the functions of the cellular elements of the blood, excepting the red blood-cells. 4. How and why do changes of temperature influence the functions of the kidneys? 5. What insects are dangerous to health? How should they be dealt with? 6. What changes result in muscle tissue following a diminished blood-supply? 7. What happens if the thyroid gland is removed? 8. What part of the brain is affected when a patient has aphasia? 9. How is acidity of the stomach maintained? 10. Describe the method of counting blood-cells.

Colorado October Report

Dr. David A. Strickler, secretary of the Colorado State Board of Medical Examiners, reports the oral and written examination held at Denver, Oct. 6, 1914. The total number of subjects examined in was 8; total number of questions asked, 80; percentage required to pass, 75. The total number of candidates examined was 4, including 1 osteopath, all of whom passed. Sixteen candidates were licensed through reciprocity. The following colleges were represented:

Miscellany

The Rural School and Hookworm Disease

The connection between the rural school and hookworm disease is a close one. Dr. John A. Ferrell, assistant director of the International Health Commission, Washington, in a recent bulletin of the United States Bureau of Education (1914, No. 20) remarks that it has been found that the rural schools are the greatest mediums for the spread of the infection and the most important protective agencies against it. Records show an average infection among rural children of school age running as high as from 70 to 90 per cent. in whole counties, the schools being apparently the distributing centers for the disease. In a number of states, the state departments of health and education have cooperated to fight the disease. For the schools of Virginia a "health catechism" has been prepared in which the germ theory of disease, general sanitation, hookworm, tuberculosis and typhoid are taken up. The North Carolina State Department of Education has published a number of bulletins on health for the use of schools including one on "Ground-Itch or Hookworm Disease and Soil Pollution." Alabama and Kentucky have issued special bulletins on health subjects, including hookworm, for school use. In 1910-1911 all county teachers' institutes in Kentucky had lectures by health officers, and in 1913 lectures were given in all the Kentucky summer institutes by an expert furnished by the State Board of Health. In Arkansas the State Department of Public Instruction has cooperated closely with the work of the Rockefeller Sanitary Commission and the State Board of Health. One of the most successful ways of emphasizing the value of special instruction about hookworm disease is to include the subject in the state and county examinations for teachers' licenses. This is done in North Carolina.

Dr. Ferrell remarks that one particularly effective method of the control of hookworm disease by state departments of education has not been fully utilized. Wherever regulation of schoolhouse grounds has been centralized in the hands of the state authorities, sanitary disposal of filth on school premises may be insisted on. Virginia and North Carolina have taken advantage of this opportunity. No schoolhouse in these states will be accepted unless it fulfils state requirements as to sanitation. With a state system of medical inspection and with state authorities empowered to condemn the water-supply, hygienic features of the schoolroom, privies, etc., it would be possible to do much toward the elimination of hookworm and other preventable diseases. Emphasis is laid on the importance of making the school itself a model of sanitation.

It is remarked that the individual teachers have, in most cases, been of great assistance in the hookworm campaign not only in disseminating information on the subject but also in influencing children to submit to examinations. The teachers have usually taken the initiative in being examined and have let the fact be known. The children and, in many cases, the other members of the children's families, have followed the example thus set. Literature on hygiene and sanitation has been distributed from the state department of health and education through the medium of the teachers. Health topics have also been made the subject of essays and of public school debates.

The Syphilis Index

Five years ago B. P. Sormani of Amsterdam pointed out a number of sources of possible error in interpreting the findings with the Wassermann test (Sormani, B. P.: Ned. Tijdschr. v. Geneesk., 1901, ii, 1338; Arch. f. Dermat. u. Syph., 1909, xcviii, 73; Ztschr. f. Immunitätsforsch. u. exper. Therap., 1911, xi, 243; Ned. Tijdschr. v. Geneesk., 1913, i, 1700; Hammarcher, J. F. M.: Ned. Tijdschr. v. Geneesk., 1912, ii, 1203). He emphasized that a correct oversight of the actual condition could be obtained only when the test was applied both qualitatively and quantitatively, the findings then representing the actual condition of the syphilis at the time—a true index. Theoretically, during the first year this index figure should grow constantly larger for a certain length of time and then decline, the slant of the downward slope influenced by the effect of treatment. This theoretical curve was found to prevail with mathematical exactness in his study of 800 serums tested for the syphilis index, and other syphilologists in Holland have confirmed this importance of quantitative findings with the Wassermann test, and declare that the test as a guide to treatment is not to be relied on otherwise. With the ordinary technic the extract itself or the patient's serum or the combination of both may be capable of binding the complement and thus affecting the response to the test.

The specific hemolysis requires a definite amount of complement, but the complement available may vary with the concentration of the blood emulsion and with the complement content of the guinea-pig serum. These sources of error are obviated by using always fresh guinea-pig serum and by titrating beforehand the strength of the complement not only in relation to the hemolytic amboceptor but also to all the other factors involved, namely, the extract and the sheep blood. This titration is done with four sets of five test-tubes, one set with normal serum, one with the serum being examined, one with known syphilitic serum and one control set without serum. The index figure is that representing the smallest amount of extract required for complete hemolysis. By repeated serologic control in this way during the first year it seems possible to secure accurate oversight of the course of the syphilis and to know when to push treatment and when to let up on it according to the actual status. His latest summary of his technic and findings was published in the *München. med. Wchnschr.*, 1914, lxi, 69.

The Stinging Hairs of Plants

Recently Yount (The Journal, Oct. 10, 1914, p. 1315) reported sixteen cases of poisoning from *Jatropha macrorrhiza septemfida*, a small plant of the milk spurge family, growing in Arizona. The toxic properties of a related species, *Jatropha urens* (locally called "ortiga" and "chichicaste") have been discussed by Otto Lutz (*Science*, Oct. 23, 1914, p. 609). This plant, common in pastures along the Pacific Coast of Central America, on account of its poisonous effects has the reputation of being extremely dangerous. All parts, trunk, leaves, flowers and fruits, are covered with long, hard and glossy, stinging hairs, which protect the plant from cattle. The stinging hairs show the same structure as those of the common nettle (of the family *Urticaceae*), though the two plants belong to different families. The poison is produced by a cell of the epidermis which during the growth swells up, forming a goblet-shaped bulb, set into the surrounding tissue. The hair then represents a long tube, the walls of which have incrustations of silicates in the upper part and are calcified in the lower parts, so that they are very brittle and break at the lightest touch. Near the top this cell expands a little, in the form of a miniature hat with very thin walls, so that when touched, it breaks in an oblique direction, forming the point of a cannula, which enters the skin of animal or man. At the same time the poisonous liquid of the cell is discharged into the wound, and produces instantly a local inflammation. The mechanism is, in fact, the same as that of the poison fang of the snakes, and it is also similar to the cannula of the surgeon.

Lutz was poisoned by contact with about ten of the stinging hairs of ortiga, which he estimated to contain only about 0.00005 c.c. of the poison. The inflammation was similar to that produced by nettles, but the pain soon increased, the whole hand began to swell and inside of half an hour had assumed a monstrous shape. Then the left arm commenced to swell, also the right hand and arm, without having been inoculated, yet showed the same abnormal symptoms, and a very strong itching sensation was felt all over the upper part of the body. At about the same time parts of the face, around the eye and nose, swelled considerably. The itching sensation rapidly spread over the abdomen and the lower extremities and red pimples appeared everywhere. In less than an hour the poison had extended over the whole surface of the body, and its entrance into the blood current was indicated by the corresponding physiologic reaction of the interior organs. The palpitation of the heart became extremely accelerated and the mind was soon overcome by an agonizing depression. The respiration seemed to be delayed as if under a great pressure, cold sweat broke out, and the patient gave way altogether, remaining unconscious for more than an hour, except for feverish dreams. After coming back to his senses, he had several fits of copious vomiting, from which it may be surmised that the poison was slowly eliminated from the organism. The weakness, however, remained for several days. Lutz suggests that the only way of allaying the effects of the poison would be to neutralize or precipitate it by means of a prompt application of chlorinated lime, ammonia or sodium permanganate.

Book Notices

Animal Experimentation and Medical Progress. By William Williams Keen, M.D., LL.D., Professor Emeritus of Surgery, Jefferson Medical College, Philadelphia, with an Introduction by Charles W. Eliot, LL.D., President Emeritus of Harvard University. Cloth. Price, $1.75 net. Pp. 312. Boston: Houghton Mifflin Company, 1914.

No one who has followed the discussion on animal experimentation and the opposition to it as a method of scientific research can be unfamiliar with the contributions of Dr. Keen on this subject. Three of the series of educational pamphlets on Protection of Medical Research issued by the American Medical Association in the last few years are from his able pen. In addition, he has contributed many articles to leading magazines and newspapers on this subject. Scientific men desiring this valuable material in convenient and accessible form, as well as laymen earnestly seeking the truth, will welcome the publication in a single volume of Dr. Keen's many contributions on this subject. The introduction by Ex-President Charles W. Eliot of Harvard University emphasizes the scientific value of experimental research and the ethical justification for such efforts for the alleviation of human suffering. Eight of the thirteen chapters in the book are devoted to the discussion of the value of animal experimentation in the development of modern medicine and surgery, the remaining chapters being given to a discussion of antivivisectionists' methods, and corrections of misstatements made by controversial writers on this subject. Not only on account of the high scientific and professional standing of the author, but also by reason of the brilliancy, clearness and fairness of presentation, Dr. Keen's book must long remain a recognized authority on animal experimentation and its value. The student, the teacher, the practicing physician and the philanthropic layman will all find it both interesting and instructive.

Optic Projection. Principles, Installation and Use of the Magic Lantern, Projection Microscope, Reflecting Lantern and Moving Picture Machine. By Simon Henry Gage, Professor of Histology and Embryology, Emeritus, Cornell University, and Henry Phelps Gage, Ph.D. Cloth. Price, $3. Pp. 731, with 413 illustrations. Ithaca, N. Y.: Comstock Publishing Company, 1914.

The increasing use of the stereopticon—or, more correctly, the magic lantern—both as a pastime and for more serious work is a sufficient excuse for this book, if any is needed. While there are a number of works on the subject, most of them are weak in one of two ways: Either scientific accuracy is sacrificed to practicality, or the practical is lost in a mass of abstruse technicalities. "Optic Projection" happily combines scientific accuracy with a simplicity of description that makes reading it a pleasure. The book should be of special value to the physician who is interested in projection apparatus. Whether the magic lantern is being used as a fascinating adjunct to amateur photography, or for more serious work of a scientific nature, great help will be found between the covers of this book. The use of the projection lantern with the electric current, with lime-light, with oil, gas, acetylene and alcohol lamps, is described in detail, separate chapters being devoted to the various illuminants. The projection of images of opaque objects, the preparation of lantern slides and the use of the microscope with the projection apparatus make material for three interesting chapters, while considerable space is given to drawing and photography with projection apparatus. Motion pictures, the projection room and screens and the optics of projection, also are described in turn. The last chapter of the book deals with the use of projection apparatus for demonstrating normal vision and refractive eye defects. An appendix gives a brief history of the development of projection apparatus, with a bibliography on projection. At the end of each chapter is a summary of its subject matter paragraphed in parallel columns telling what to do and what to avoid. The scope of the book is both practical and scientific; the language simple but accurate.

Food Products. By Henry C. Sherman, Ph.D., Professor of Food Chemistry, Columbia University. Cloth. Price, $2.25. Pp. 594, with illustrations. New York: The Macmillan Company, 1914.

This book is a compilation of a well-arranged mass of data concerning what we eat, together with recent scientific investigation and food legislation. After an elementary consideration of the chief constituents of foods, there is a chapter on the principles of food legislation, which embodies study of the food and drugs act, as well as state and municipal control. Following this, beginning with milk, chapters are devoted to various types of foods. The discussions are practical, timely and interesting. Especially important is the author's analysis of the duties of milk commissioners and milk inspectors. The holding method of pasteurization is commended highly, and the "flash" method is condemned. Following the chapter on milk—and the same plan is followed for other subjects—is a list of references to approved literature on the subject, including articles that have appeared in the current volumes of good American publications. There are numerous tables which give in compact form a vast quantity of comparative information concerning the products studied, and there are numerous illustrations and charts showing distribution and process of manufacture of some of the less known materials.

Worry and Nervousness or the Science of Self-Mastery. By William S. Sadler, M.D., Professor of Therapeutics, the Post-Graduate Medical School of Chicago. Cloth. Price, $1.50 net. Pp. 535, with 21 illustrations. Chicago: A. C. McClurg & Co., 1914.

This book may be classed as one of the better type of books written for the neurotic public. There is included in it a wealth of sane advice, and the author's experience is such as enables him to speak from a truly practical point of view. The average individual to whom the book is given will not in all probability give it the real study which its contents deserve. It is questionable whether the neurotic patient can be prevailed on to concentrate his mind on any literature. The book takes a modern sane view of the field of psychanalysis. Some of the illustrations cannot be said to add anything to the value of the work. However, it is a book which, like few others of its class, can safely be recommended to the clientele for which it was prepared.

The World's Social Evil. A Historical Review and Study of the Problems Relating to the Subject. By William Burgess, with a Foreword by Dr. Graham Taylor. Supplementary Chapter on a Constructive Policy, by Judge Harry Olson, Chief Justice, Municipal Court, Chicago. Cloth. Price, $1.50 net. Pp. 401. Chicago: Saul Brothers, 1914.

The foreword is essentially a review of the book. There is much material in the book, but the arrangement is not the best, and the various portions are rather disconnected. Dr. Taylor believes that the public sale of the book is a move in the right direction for only through publicity will the cure come. Physicians will doubt many of the theories presented in the chapter entitled "The War and the Weapons." Scriptural and Shakespearean quotations are not scientific evidence. The book will probably have a wide sale, for what is suppressed or forbidden is by human nature most desired.

Medicolegal

Reporting to Medical Club Patient as Slow Pay

(*McDonald vs. Lee (Pa.), 91 Atl. R. 135*)

The Supreme Court of Pennsylvania affirms a judgment on a verdict directed for the defendant, a physician, who sued for damages for an alleged libel. The court says that it appeared from the record that a number of physicians in Carlisle determined to prepare, for their own use, a list of the names of patients who were slow in making payment for medical services rendered to them. The information was for the benefit of the members of the medical association only, and there was no understanding between them that professional services should be refused to those whose names appeared on the list. The defendant was a member of the association, and she furnished to the secretary, among other names of persons whom she regarded as able to pay, but who were slow in making payments for services, the name of the plaintiff. The list of names thus reported as slow pay was printed by the association, with the number of the physician who furnished the name added. There was nothing on the face of the publication to indicate its purpose, and no one but a member could understand its meaning. The publication was considered confidential, and was limited to the members of the medical association. In the plaintiff's statement of claim there was no averment of any special damage to the plaintiff resulting from the publication, nor was there any proof of such damage. On the trial, at the close of the testimony, the judge gave binding instructions in favor of the defendant, on the ground that the communication was a privileged one, and there was no evidence of malice, nor was any special damage shown. The alleged libel was a communication made in confidence to and for the exclusive use of the members of the Carlisle Medical Club. It had reference only to the manner in which the plaintiff made payment for services rendered. It did not appear that, by reason of the report, credit was refused to the plaintiff, or that any member of the association refused to serve him in a professional way.

It was the duty of the trial court to determine whether or not the words used were libelous per se, or in and of themselves. If they were not, then, in the absence of special damage, binding instructions were proper. The Supreme Court can see no sufficient ground for holding the publication to be libelous per se, or in and of itself. If it became actionable by reason of some special damage occasioned thereby, that fact should have been alleged in the declaration, and proof thereof should have been offered on the trial. It was shown that the words used with respect to the plaintiff did not go beyond imputing to him slowness in the payment of his bills, and under the evidence it could hardly be claimed that he was prompt in the discharge of that duty. The accusation was not so serious in its character as to be fairly regarded as in itself libelous, and, if any injury was occasioned to the plaintiff thereby, it did not appear from the testimony. The good faith of the defendant in making the communication was not questioned. She had an interest in the subject-matter, and the communication was made to persons having a corresponding interest in the subject. In none of the assignments of error does the Supreme Court find anything of substantial merit or that would warrant a reversal of the judgment for the defendant.

Sanatorium Record Kept by Physician

(*Mahegan vs. Faber (Wis.), 149 N. W. R. 397*)

The Supreme Court of Wisconsin says, in this action to recover damages for the death of a man caused by an automobile, that he was a patient at a tuberculosis sanatorium for a time. He was examined by the superintendent of the institution when he was admitted, and from time to time thereafter, and a record was made of such examinations by the superintendent, a physician. The defendant sought to introduce the record in evidence, but the trial court excluded it. The superintendent testified that the record contained the information that he obtained from the patient for the purpose of treating him as a physician. It is quite obvious that the record made by the physician for this purpose was properly ruled out under the statute relating to privileged communications.

Hernia as a Result of a "Fortuitous Event"

(*Zappala vs. Industrial Insurance Commission (Wash.), 144 Pac. R. 54*)

The Supreme Court of Washington affirms a judgment in favor of the plaintiff for a hernia claimed to have been received under circumstances entitling him to relief under the workmen's compensation act. The claim was rejected by the commission on the ground that the hernia, derived from trying to start a heavily loaded truck, was not the result of some "fortuitous event" within the language of the act, which provides that the words "injury" or "injured," as used therein, refer only to an injury resulting from some fortuitous event as distinguished from the contraction of disease. The court says that the sustaining of an injury while using extreme muscular effort in pushing a heavily loaded truck is as much within the meaning of a fortuitous event as though the injury were the result of a fall or the breaking of the truck. To hold with the commission that if a machine breaks, any resulting injury to a workman is within the act, but if the man breaks, any resulting injury is not within the act, is too refined to come within the policy of the act as announced by the legislature in its adoption and the language of the court in its interpretation. The machine and the man are within the same class as producing causes, and any injury resulting from the sudden giving way of the one, while used as a part of any industry within the act, is as much within the contemplation of the act as the other. When the commission admits that the breaking of the truck because of the application of unusual force with resultant injury to the workman is covered by the act, then it must admit that the tearing of muscles or the rupture of fibers, or whatever it is that causes hernia, while exercising unusual effort, is likewise covered by the act; for there can be no sound distinction between external and internal causes arising from the same act and producing the same result. The American cases arising out of acts of this character sustain this court's conclusion that there is no distinction between the accident and a fortuitous event.

Waiver of Privilege by Plaintiff

(*McKenney vs. American Locomotive Co. (N. Y.), 149 N. Y. Supp. 826*)

The Supreme Court of New York, Appellate Division, Third Department, reverses a judgment entered in the plaintiff's favor, for error in excluding the testimony of a physician, sought to be adduced by the defendant, as to the condition of the plaintiff's eye prior to the accident by which he claimed to have been injured. The court says that a physician examined in behalf of the plaintiff may be asked on cross-examination whether he had not treated the patient for the same disease at a prior time. He may also be asked respecting what he learned on a subsequent examination, after his treatment at the time of the accident had ceased. This, of course, is on the assumption that the privilege had been waived by the plaintiff. The plain import of the plaintiff's testimony in this case was that the physician declined to treat his right eye after the accident because of its swollen condition, making it impossible for him to give such treatment. It would seem clear that this testimony would authorize the physician to swear that the eye was not swollen at that time, and also to swear what was its actual condition. Such was the evidence sought to be given by the defendant, and ruled out, as this court thinks, erroneously. That this testimony was very material was shown by the history of the case. The claim was that the injury produced a cataract. That there was a cataract in the eye was admitted. The defense claimed that it was a congenital cataract, one which had been there from birth, and not one caused by the accident. If so, the defendant should not be required to pay for the plaintiff's misfortune.

Society Proceedings.

CHICAGO GYNECOLOGICAL SOCIETY

Meeting Held Dec. 18, 1914

Case of Pseudodiphtheritic Cystitis

The President, Dr. Robert T. Gilmore, in the Chair

Dr. Arthur Curtis: A woman, aged 52, had had three normal births without any complication. A catheter or sound had never been passed. The history showed nothing that would indicate an artificial introduction of the organism into the bladder or kidney. About ten years ago two of her children had a virulent diphtheria. There was nothing of interest in the woman's history until the bladder trouble began, about two years ago. At that time she began to have some distress, but not extremely marked. A year ago last April there was noticed for the first time a marked distress on urination, the passage of small concretions from the bladder, and at quite frequent intervals blood in the urine, intimately mixed at times, and at other times passed without the amount of urine being in proportion to the blood. At the time of her first cystoscopic examination by me three or four months ago, the bladder picture was quite unusual. This was the first time any instrument had been passed into the bladder. Except for one very small area in the fundus, the bladder wall was absolutely covered with a thick membranous deposit. This membrane hung down from the fundus of the bladder, from the anterior walls and sides, just as stalactites hang from the walls of a cave. It was difficult to judge the thickness of the membrane, because it covered the entire bladder wall, but in some places it seemed almost an inch in thickness. The ureteral orifices could not be seen. The membrane could not be dislodged by massage or other manipulations. The bladder was washed out, and pieces of membrane that came away were examined, and showed a culture resembling the diphtheria bacillus. Cultures made from the urine showed a pure culture of the same organism. There seemed no doubt that we had to do with an absolutely pure infection with an organism of the diphtheria group, that is, the pseudodiphtheria bacillus. Vaccines were given for a period of about three months, with only moderately satisfactory results, so far as the symptoms were concerned. Two weeks ago the patient was again examined by cystoscope, at which time it was found that the membrane had disappeared in a great part of its extent. Dr. Watkins then performed a cystotomy. Very deeply in the mucosa of the bladder the examining finger found calcareous crystals, varying in size from ⅛ to ¼ inch in diameter.

DISCUSSION

Dr. Thomas J. Watkins: These crystal deposits were embedded so deeply in the mucous membrane that it was difficult to dislodge them. Some situated superficially were dislodged with the finger, and some were scraped away with a blunt curet, but it did not seem advisable to try to remove them all, on account of the great amount of traumatism which such a procedure would entail. We depended on drainage and the use of benzoic acid to get rid of the deposits that were deeply embedded. In these cases of cystotomies in the female it is difficult to obtain perfect drainage. With an ordinary vesicovaginal fistula it is difficult to prevent all the urine from escaping, and in these cases one may make an incision long enough to get two fingers in, and yet the urine will not all come away. It is a problem, therefore, whether it is better simply to depend on a linear incision, or to remove considerable of the mucous membrane of the vagina, so as to get drainage. It is impracticable to put any drainage material into the bladder, on account of the irritation which results. This woman has been kept on about 20-grain doses of benzoic acid daily, and the urine has become acid and more clear.

Dr. Arthur Curtis: In the majority of instances in which the patient is able to empty the bladder thoroughly, the establishing of drainage through a cystotomy or by irrigation is not ordinarily indicated. Either procedure is indicated only under very exceptional circumstances, such as in cases in which there is retention of urine.

Ovarian Tumors in Pregnancy; Report of Case of a Solid Tumor

Dr. W. C. Danforth: The patient, a woman aged 32, was first seen by me when pregnant about three months. On examination, a mass about the size of a fetal head, hard and freely movable, was found on the left side of the abdomen. The fundus of the uterus was easily palpable about two fingers' breadth above the pubis. Five months earlier the patient had noticed a mass in the lower part of the abdomen, which she said had gradually increased in size. There had been slight bleeding about one week before I first saw the patient. A diagnosis was made of ovarian cyst accompanying pregnancy, and operation advised, consented to, and performed September 9, the tumor being excised. There were no adhesions; the tumor was attached to a pedicle about 4 inches long. It weighed 292 gm., was 10.5 cm. long, 8.5 cm. broad and 6.5 cm. thick. It was of an elongated spheroidal shape, white, firm and hard. The surface was covered by a thin, firm, glistening capsule. The cut surface was even and homogeneous, some tiny spaces being seen, which were probably due to the dropping out of small particles of tissue which had undergone myxomatous degeneration. Microscopically, the mass proved to be a fibromyoma, which had undergone myxomatous degeneration. One portion of the mass was composed of almost pure unstriped muscle tissue. The patient made an uneventful recovery. Nothing was heard of the subsequent labor, but as it was the third pregnancy, and the former labors had been normal, it is supposed that it presented nothing out of the ordinary.

Solid tumors of the ovary are not at all common, and are particularly rare in connection with pregnancy. The prognosis in these cases of ovarian tumor associated with pregnancy, so far as the mother is concerned, depends largely on the location of the tumor, the promptness with which it is recognized, and the skill of those attending the woman. The complication most to be feared is twisting of the pedicle, but these patients almost always may be saved by prompt operation. If an ovarian tumor is recognized during pregnancy, the proper mode of procedure is its immediate removal. The danger to the mother is slight and the risk to the fetus is greatly lessened. Removal by means of an abdominal incision is usually the method of preference, although a few writers urge the vaginal route. The percentage of abortion seems to be much more favorable in the cases subjected to laparotomy than in those subjected to vaginal section. If the case has been handled in any but the most aseptic manner, the tumor should be pushed up out of the pelvis, if possible, and delivery accomplished either spontaneously or operatively through the vagina. Delivery by forcefully extracting the child alongside the mass should never be attempted. If reposition is impossible, puncture or incision and drainage of the tumor, if it be a cystic one, should be done, after which delivery should be accomplished as speedily as possible, and the sac removed by abdominal incision or colpotomy within twenty-four hours. If the case is a clean one, in a well-conducted hospital, the mass may be removed at once by laparotomy and delivery accomplished by hysterotomy or from below at once. In cases in which labor has not begun, or in which there is little or no dilatation, my inclination is toward delivery by cesarean section.

DISCUSSION

Dr. Thomas J. Watkins: It would be a difficult and possibly unwise plan to set down definite rules to follow in the treatment of these cases. It should be very largely a question of determination in individual cases, depending on the facts with which we are all familiar. I think it would be unwise to remove an ovarian cyst as soon as found. The better method would be to let the pregnancy go on to term, remove the cyst, and do a cesarean section at the same time, or do the cesarean section first and then remove the tumor, to facilitate the operative technic. However, this would have to be determined in individual cases by the size of the tumor and local conditions, such as access to a good hospital.

Dr. Rudolph W. Holmes: We should not determine that we should operate in a specified manner on an ovarian tumor. It is not so much the size of the tumor as its location that is going to cause trouble during the pregnancy, or more particularly at the time of delivery. A small ovarian tumor, lodged in the culdesac, adherent, may offer insurmountable difficulties to spontaneous labor, whereas a very large tumor may be so located that without any complications or disturbances, labor will go on to a spontaneous conclusion. Therefore, it is more the location than the actual size of the tumor. There is a great deal of risk of infection in cases of dermoid cyst especially, and it is very difficult at times to determine whether we have to deal with a dermoid or not. On the suspicion of a dermoid, the sooner out the better. The ideal time to remove tumors ordinarily is at the time of labor, if they in any degree suggest interference with labor. If the tumor is to be removed at or about the time of labor, and cesarean section is to be performed, the section should be done first, because immediately with the emptying of the uterus there is a diminution of the blood supply through the vessels of the pelvis, and therefore the hemorrhage, if there is any, is more easy of control.

Dr. Channing W. Barrett: The differentiation of a solid tumor of the ovary or solid tumor of the uterus is an important one, because it is agreed that ovarian tumors should be removed nearly always when found, while fibroids of the uterus, for apparent reasons, should be left alone until they are giving trouble.

Dr. W. C. Danforth: As to the sequence of the operations, cesarean section and removal of the tumor, doing the section first and removing the tumor afterward is, in my opinion, the logical procedure.

10 Centrifuge Method to Provide Uniform Standard for Wassermann Readings. B. B. V. Lyon and J. Eiman, Philadelphia.

1. **Phenolsulphonephthalein Test.**—The observations made by Thayer and Snowden show in severe chronic nephritis, a uniformly low phenolsulphonephthalein output which, as a rule, in those instances not interrupted by an acute terminal process, decreases steadily up to the onset of uremia and is nearly or wholly suppressed from a day or two to a month before death. Acute terminal processes which may be unsuspected clinically, are common, and here a sudden diminution in the elimination of phenolsulphonephthalein may come on in cases in which the percentage previously excreted is not so low as to appear menacing. In not a single instance have the authors met with a case of severe chronic nephritis with a good phenolsulphonephthalein elimination. Chronic passive congestion (cardiac disease) results often in a considerable reduction in the two hours' elimination of phenolsulphonephthalein. The results are very variable in individual cases. In marked decompensation the phenolsulphonephthalein output may be reduced to but a trace in two hours; but the excretion is, as a rule, rapidly restored with the reestablishment of circulatory compensation. These observations are in agreement with the experimental studies of Rowntree and Fitz.

In the few instances of chronic nephritis of moderate extent which are included among these cases the excretion of phenolsulphonephthalein was uniformly considerably reduced. All of these cases, however, were associated with chronic passive congestion of considerable extent, but the percentage of phenolsulphonephthalein was lower than might have been expected with an uncomplicated passive congestion. In one instance of acute nephritis and in one instance of pure amyloid disease the phenolsulphonephthalein excretion was greatly reduced. The cloudy swelling observed in acute infections was in some instances associated with considerable reduction in the phenolsulphonephthalein output.

2. **Gastric Ulcer and Carcinoma.**—Of 399 cases of gastric cancer from which the tissue containing the primary lesion was resected in the Mayo clinic, 4.8 per cent. showed ulcer with doubtful cancer in the border, 15.8 per cent. showed ulcer with positive early cancer in the borders only of the lesion, 36.8 per cent. showed ulcers with advanced cancer, while 42.6 per cent. of the cases showed cancer in which the previous ulcer formation is doubtful. Of 46 cases of gastric cancer from which the tissue containing the primary lesion was obtained at necropsy, 1 case (2.2 per cent.) showed an ulcer with doubtful cancer, 7 cases (15 per cent.) showed ulcer with advanced cancer while in 38 cases (82 per cent.) the evidence of ulcer previous to cancer formation is doubtful.

The clinical and pathologic data in relation to the development of gastric cancer or gastric ulcer are in close agreement: (a) with regard to the average age at operation; (b) with regard to the average period of previous history suggestive of ulcer, and (c) with regard to the average number of months of acute history. To Wilson and McDowell it seems probable, from a careful study of the clinical and pathologic evidence of this series of cases, that gastric cancer rarely develops except at the site of a previous ulcerative lesion of the mucosa.

5. Abstracted in The Journal, June 13, 1914, p. 1924.

7. **Absorption of Protein and Fat.**—Absorption studies after resection of the lower half of the small intestine are reported by Palmer. He found the loss of nitrogen in the stools is four or five times that of normal individuals. The loss in fat in the stools is five to six times the normal loss. A high urinary indican, 800 mg. is reported. Ammonia forms a much larger part of the urinary nitrogen than in normal individuals. This is probably due to the extensive putrefaction taking place in the intestine. The success with which a large portion of the intestine may be removed depends to a large degree on the condition of the intestine remaining. This fact Palmer believes to be important and should be considered carefully before extensive resections are undertaken. Palmer says that a diet low in fat and moderately low in protein should be given in cases in which much intestine has been removed.

9. **Diastolic and Pulse-Pressure.**—Of forty-nine cases of myocardial insufficiency at all ages observed by Warfield the average pulse-pressure was 40 mm. The highest was 70, the lowest 15 mm. He has seen cases of myocardial disease with normal blood-pressure figures, five minutes before death. In seventy-five cases of chronic nephritis the average pulse-pressure was 62 mm. The ages of the patients ranged from 10 to 82 years. The highest pulse-pressure, 130 mm. occurred in a man, aged 55 years. A child, aged 10 years, had at one period of her stay in the hospital systolic 186, diastolic 154, pulse-pressure 32. She left the hospital improved and with

130, 80, 50 as her pressure. The most consistent low pulse-pressures were in the advanced cases of pulmonary tuberculosis. Also in typhoid during the third, fourth and fifth weeks, when the fever lasts that length of time, the whole pressure picture is reduced, but the pulse-pressure is reduced relatively more than diastolic pressure.

Warfield has taken for low pulse-pressure any below 30, for high any above 50. The pulse-pressure in aortic insufficiency is always large; in fact, it is usually the largest in any disease. In chronic nephritis the pulse-pressure is always high in the compensation stages. In some forms of arteriosclerosis the pulse-pressure is high. In myocardial insufficiency it varies. If the heart is large there is increased pulse-pressure, if the heart is small there is decreased or normal pulse-pressure. In pulmonary tuberculosis the pulse-pressure is low in the advanced cases. In the early cases the blood-pressure picture, as a rule, is normal or generally decreased. If the heart is large naturally the blood-pressure picture takes on more the form of that in cases of enlarged heart with general depression of the blood-pressure picture. In the acute fevers the pressure picture in the initial stages shows no particular changes. As the cases develop the whole pressure picture as a rule shows a general depression and a low pulse-pressure usually means a badly diseased heart and is an unfavorable prognostic sign.

In general when the systolic pressure is normal, increased pulse-pressure signifies peripheral dilatation. When the systolic pressure is high the increased pulse-pressure is to be regarded as normal and has no special significance. Decreased pulse-pressure or even normal pulse-pressure means marked peripheral constriction, and is therefore, an unfavorable prognostic sign. With low systolic pressure increased pulse-pressure occurs in practically only one condition, aortic insufficiency. With normal systolic pressure gradually decreasing pulse-pressure usually means cardiac failure. The condition is seen often in the later stages of the high systolic increased pulse-pressure cases. With low systolic pressure increased pulse-pressure usually means general cardiac weakness, as seen in febrile conditions or in convalescence from long illnesses or in cachexia of malignant disease.

25. **Studies in Caffein.**—Fifteen patients suffering from advanced myocardial diseases were selected by Taylor for this study. Every case showed some sign of broken compensation at the time of the experiment, and thirteen gave evidence of retained body fluid. Dyspnea was present in 14 cases; edema of the extremities in 13 cases; ascites in 10 cases; hydropericardium and hydrothorax, single or double, in 6; tender pulsating liver in 6. Other common symptoms were cough, frontal headache, weakness, dizziness and substernal pain. All patients were kept in bed on a constant diet. Of the 15 cases the results were excellent in 8, moderate in 4, and there was no result in 3. In one of the cases in which there was no result, the vomiting and loss of sleep even on small doses more than balanced any possible good that the drug could have done. All the cases with limited results showed the nervous signs, so the absorption of the drug was assured.

In five of these cases a second admission to the hospital or a return of symptoms while they were still in the instiution made it possible to try the comparative therapy of theobromin sodium salicylate under the same conditions and on the same heart on which the caffein action had been tested. Its action on the urinary outflow is more prompt than that of caffein and the diuresis is larger. The theobromin sodium salicylate action is equally well sustained and usually at a higher level than the caffein. When caffein has a depressing effect on the vasomotor system and lowers the blood-pressure, theobromin sodium salicylate first elevates the pressure and then later lowers it.

Eighty grains a day is a normal clinical dose. Patients will tolerate this dose easily. Not only is the theobromin sodium salicylate action prompter, much stronger and equally well sustained, but it exhibits none of the gastric and nerve disturbances attendant on caffein. In cases with edema, the diuretic effect of caffein may be taken safely as a sign of an improved mass movement of blood, which is the result desired. From this point of view it is evident that small doses are not adequate. The best results are obtained with full doses.

Therefore, Taylor concludes that in myocardial insufficiency with retained body fluid, caffein causes: a moderate increase in the urine output with a proportional loss of body weight. This increase reaches its maximum on the fourth day; a drop in both the systolic and diastolic blood-pressures which may stand in a causal relation to the diuretic coefficient, contrary to the usual teaching; a slight (3.6 per cent.) temporary rise in the pulse-rate, but no permanent change in either the pulse or respiratory rate; a moderate relief of the cardiac symptoms; the constant appearance of distressing nervous and gastric symptoms. The clinical diuretic action of caffein may be better performed by large doses of theobromin sodium salicylate without the unpleasant side effects.

26. **Glycosuria as Influenced by Diet, Body Temperature and Purity of Ether.**—It is claimed by Ross and Hawk that the reduction of body temperature during ether anesthesia does not of itself cause glycosuria. The reduction to a minimum of the oxygen content of the ether vapor inhaled does not cause glycosuria. The response of the animal body to "dehydrated" ether (that is, ether from which aldehyd and other impurities have been removed) in so far as glycosuria is concerned, is no different from the response to the ether ordinarily used for anesthetic purposes. The inhalation of ether administered by the cone method causes a more pronounced reduction in body temperature than does the

inhalation of the same kind of ether for a similar period when administered by the so-called improved method. The dryness of the ether vapor in the cone method is the contributing factor. The inhalation of either "dehydrated" or common ether for a period of two hours by dogs fed a carbohydrate-free diet was in every instance accompanied by glycosuria. When the same animals were fed a mixed diet glycosuria was not in evidence. There was no evidence of "emotional" glycosuria, the factor regulating the occurrence or non-occurrence of glycosuria in every instance being a dietary one.

28. **Two Hepatic Functional Tests.**—The results of Sisson's studies with phenoltetrachlorphthalein show that the normal output of the dye in the feces is about 35 per cent. The inapplicability of the test to cases with evidence of biliary stasis makes its scope limited. The galactose test, however, may be of great value in differentiating icterus catarrhalis from other hepatic conditions showing biliary stasis. It is rarely positive in cases of cirrhosis of the liver showing no evidence of biliary stasis. There is no apparent relation between the excretion of galactose and phenoltetrachlorphthalein. Judging from the experimental studies and from the clinical observations noted up to this time, it seems to Sisson that a more exhaustive application of the test is justified. It offers a means of diagnosing certain cases of cirrhosis of the liver and of neoplasms of this organ. The results obtained may also be of some prognostic value.

29. **Effect of Theobromin Sodium Salicylate in Acute Experimental Nephritis.**—So far as renal function may be judged from phenolsulphonephthalein excretion in acute experimental nephritis produced by uranium in the rabbit, Christian says, there is no evidence that theobromin sodium salicylate exerts any constant beneficial action. In the severer forms there is almost no evidence of beneficial action; in the very mild forms there is occasionally evidence of beneficial action, but this is too inconstant to justify the conclusion that theobromin sodium salicylate really improves renal function even in the very mild forms of acute nephritis. The results obtained in the rabbit are in accord with the common clinical teaching that diuretics are not indicated in acute nephritis in man; but they are no proof of the correctness of this teaching, for results obtained in rabbits cannot be directly read in terms of man. However, they would seem to lend some further support to the view based on clinical observation that diuretics are not indicated in acute nephritis.

31. **Family Periodic Paralysis.**—The clinical history and a metabolism study of seven days' duration on the Folin diet is described by Diller and Rosenbloom in a case of family periodic paralysis. They studied the nitrogen metabolism and urinary nitrogen partition (total nitrogen, urea nitrogen, ammonia nitrogen, uric acid nitrogen, creatinin nitrogen and undetermined nitrogen), the sulphur metabolism and urinary sulphur partition (total sulphates, inorganic sulphates, ethereal sulphates and neutral sulphur), the calcium, magnesium, phosphorus and fat metabolism. The only decided metabolic changes found was a marked decrease in the amount of creatinin and creatinin nitrogen excreted in the urine and a marked increase in the amount of undetermined nitrogen of the urine.

32. **Incidence of Status Lymphaticus in Dementia Praecox.**—Emerson examined 208 men from 16 to 50 years of age definitely classed as having dementia praecox, among whom sixty-one were found to exhibit the typical physical characteristics of status lymphaticus (29.3 per cent.); 147 were found to be physically normal (70.6 per cent.).

33. **Artificial Pneumothorax.**—The authors' report deals with experiences and results with artificial pneumothorax, and with a series of gas analyses and animal experiments in regard to the use of air or nitrogen. During the past two years the attempt has been made to produce an artificial pneumothorax in eighty-three patients with advanced pulmonary tuberculosis. In two cases the method of Brauer was attempted, in all others that of Forlanini. The apparatus and method of procedure were practically similar to those so well described by Robinson and Floyd, and by Hamman and Sloan.

The authors conclude that the procedure of artificial pneumothorax is of undoubted value in many advanced cases of pulmonary tuberculosis. The dangers in its application with proper precautions would seem negligible. The necessity for keeping up the compression over a long period of time is a serious drawback, as is also the possible annoyance to the patient of the development of fluid. They urge that for the present every known method should be very thoroughly tried out before suggesting pneumothorax to patients. The compression should be kept up for probably several years. The authors' experiments on monkeys showed that little if any advantage is to be gained by the employment of nitrogen rather than atmospheric air for the production of artificial pneumothorax.

34. **Effect of Strychnin, Caffein, Atropin and Camphor on Respiration.**—Edsall and Means summarize their findings as follows: Strychnin: No action on the respiratory center or circulation, possibly an increase in metabolism. Caffein: Stimulation of respiratory center, moderate increase in metabolism, no effect on circulation. Atropin: Marked increase in metabolism, in doses large enough to cause the classical action on the circulation. Marked drop in the calculated values for alveolar carbon dioxid and rise in alveolar ventilation. Whether these latter effects are due to stimulation of the respiratory center or to changes in the dead space is not clear at the present writing. Camphor: The results not agreeing, no conclusions are justifiable.

42 *Subnormal Temperature in Tuberculosis. A. K. Stone, Boston.
43 Coccygodynia: Causes and Treatment. R. Duffy, Tampa, Fla.

41. **Analysis of Recoveries at Psychopathic Hospital.**—A second series of 100 cases, considered especially from the point of view of psychopathic nursing of brief manic-depressive excitements and of hysteric and other deliria is presented by Haines. Forty persons about 40 years of age recovered. There were three in the fifth decade who were not alcoholic, and four above 50 who were not alcoholic. The list of the second 100 recoveries includes 111 admissions and 106 recoveries. Nine patients were admitted twice and one three times. Eighty-two of the total number of admissions are psychoses directly due to alcohol.

Of the alcoholics only 21 per cent. were females, and all these were married, while only 45 per cent. of the alcoholic males were married. Alcoholic hallucinosis requires, on the average, twice the time necessary for delirium tremens to clear up. Eighteen and 7 per cent. of all "recoveries" among alcoholics came voluntarily to the hospital. Twenty-six of these 106 "recoveries" or 24 per cent. are from psychoses not attributable to alcohol. The large number of patients suffering from serious disturbances of metabolism and at the same time insane but recoverable, as shown by the outcome, demonstrates the unique field of service of psychopathic nurse and psychopathic hospital. Anomalous Wassermann reactions, in some cases in which the psychoses seem in no ways attributable to syphilitic infection, raise interesting problems in psychiatry. Others, in which alcohol and syphilis seem to work together, open up problems in the permutations of the symptoms of two groups.

42. **Subnormal Temperature in Tuberculosis.**—In tuberculosis cases, Stone says that at a certain period of the disease, usually succeeding the active febrile stage, there is often a period when the temperature curve shows marked excursions in the subnormal, the temperature at no time rising above 98.6 degrees, and rarely fully reaching this point. The patients during this period of subnormal temperature are usually improving and making distinct gains, but it takes very little to give them exacerbations of real febrile temperature, lasting from a few hours to a few days. This period of subnormal temperature may last for weeks, the curve becoming less and less irregular if the improvement continues, and finally becoming a continuous straight line at 98.6 degrees. Until this latter condition is found, Stone does not allow his patients much more latitude in their movements than while in an active febrile stage. When there is a constant variation of the temperature from the normal, it means that there is a pathologic process going on in the body, which may not be accounted for; that, however, is ignorance, and not because the patient is in a truly normal condition. The persistent subnormal temperature has become to Stone a part of the regular course of a case of tuberculosis that is on the whole progressing favorably. It does not have prognostic value, as a patient may from this stage again become febrile; although on the whole the tendency is, under favorable conditions, for the temperature curve to become a practically straight line.

46. **Unsuccessful Attempt to Provoke Vomiting.**—After using an esophageal expanding hair probang unsuccessfully four times in his case Walter decided to try emesis, hoping to dislodge the substance in this way. Titillation of the throat and epiglottis was tried several times without result. The patient was given an emetic dose (4 to 6 drams) of syrup of ipecac. In thirty minutes he was given 20 grains of zinc sulphate, followed in fifteen minutes by a large tablespoonful of pulverized mustard in an equal quantity of lukewarm water. In ten minutes 20 grains of zinc sulphate was repeated and in five minutes more mustard (amount not certain). At this time two pints of lukewarm water were given, all of which produced no emesis. In ten minutes 1/10 grain of apomorphin hydrochlorate was subcutaneously injected with no result, except in fifteen minutes a tendency to be a bit stupid. A second dose of apomorphin of 1/10 grain was given without the slightest nausea.

Walter washed the stomach out with two quarts of warm water, hoping at the time for some reaction by means of the tube. The man became weak, relaxed and was perspiring from the apomorphin and the ordeal. He was put to bed and allowed to sleep. In one hour and thirty minutes he awakened gulping (not vomiting) up a piece of tough, irregular roughened cartilage the size of an egg with entire relief. This case is of interest, first, because so large a mass could exist and not be disturbed by probang or stomach tube unless a diverticulum were present (symptoms of which there were none other than the above); second because of the quantity and the variety of emetics given without the slightest result, and third because of the manner in which the cartilage was finally ejected.

56 *Lesions Produced by Bite of "Black Fly" (Simulium Venustum). J. H. Stokes, Ann Arbor, Mich.

56. **Lesions Produced by Bite of Black Fly.**—The principal positive result of the work detailed by Stokes has been the experimental reproduction of the lesion produced by the black fly in characteristic histologic detail by the use of preserved flies. The experimental lesions not only reproduced the pathologic picture, but followed a clinical course, which in local symptomatology especially, tallied closely with that of the bite. This the author interprets as satisfactory evidence that the lesion is not produced by any living infective agent. The experiments performed do not identify the nature of the toxic agent. Tentatively they seem to bring out, however, the following characteristics: The products of alcoholic extraction of flies do not contain the toxic agent. The toxic agent is not inactivated by alcohol, is not destroyed by drying fixed flies, is not affected by glycerin, but is, if anything, more active in pastes made from the ground fly and glycerin, than in the ground flies as such. It is rendered inactive or destroyed by hydrochloric acid in a concentration of 0.25 per cent., is most abundant in the region of the anatomic structures connected with the biting and salivary apparatus (head and thorax), is not affected by a 0.5 per cent. solution of sodium bicarbonate nor by exposure to dry heat at 100 C. for two hours. It is destroyed or rendered inactive in alkaline solution by a typical hydrolytic ferment pancreatin. Incomplete experimental evidence suggests that the activity of the toxic agent may be heightened by a possible lytic action of the blood serum of a sensitive individual, and that the sensitive serum itself may contain the toxic agent in solution.

The following working theories have suggested themselves to Stokes: First, the toxin may be an alkaloidal base, toxic as such, and neutralized after injection by antibodies produced for the occasion by the body. Second, it is conceivable that the injected saliva of the fly does not contain an agent toxic as such; that, like many foreign proteins, it only becomes toxic when broken down. Third, lytic agents in the blood serum may play the chief rôle in the liberation of the toxic agent from its non-toxic combination. This view is the one to which the author inclines as the one which most adequately explains the phenomena. Fourth view, that the initial injection of a foreign protein by the fly (namely, with the first bite) sensitizes the body to that protein.

99. Abstracted in The Journal, June 6, 1914, p. 1839.

101. **Care of Abdomen in Childhood.**—An infant under 6 months of age, according to Mosher, should not find out that there is any posture of the body other than the horizontal, and his acquaintance with the out-of-door world would be better made from a basket on a balcony, fire-escape, or even window (safely caged), than from a bumping baby carriage. When the abdomen is sufficiently developed to safely permit the sitting posture, and the child shows an interest in things around him, some modification of the "go-cart," supplied with proper springs and a seat on which a child can balance easily, is better than the present baby carriage into the soft cushions of which he sinks, losing and gaining his equilibrium as his flexible little spine wobbles hither and yon. Habitual physical quiescence with little mental entertainment not only makes happy babies, but tends to keep them normal. Little is needed for the development of the abdominal wall at this time, outside of perfect freedom of motion during waking hours. Petticoats, pinning blankets, and diapers should be so loosely fastened that they cannot interfere with the movements so important to a baby's digestive apparatus.

Mosher emphasizes that it is of great importance that infants shall early learn to lie on the abdomen as easily as on the back: no one position, however, should be permitted to become habitual. From the time a child has learned to walk easily, there is little danger of abdominal injury until school life begins. His play instinct keeps him constantly changing his posture and varying his movements. There are a few kinds of play, however, that may prove injurious. Those which encourage the sitting posture on the floor are not desirable nor are those which demand a stooping posture.

Many of the garments for children of school age are so shaped that they tend to produce round shoulders and flat chests with their accompanying encroachment on the abdomen. The American Posture League is taking up the subject of children's garments, and has already perfected a model known as the "Good Posture Suit," for boys, which carries the American Posture League label. Gymnastic exercise with especial reference to the development of the chest and abdomen is of great importance during the school life of children.

102. **Fractures of Neck of Femur.**—The following procedure is employed by Walker: A careful examination is made of the patient's condition in order to determine the wisdom of giving an anesthetic for a period of twenty minutes, this time being required for the application of the plaster bandage. As soon as the anesthetic permits complete relaxation, a gentle examination is made of the fracture and frequently crepitus is found in those patients in whom impaction is thought to be present.

The patient is lifted to a pelvic support, preferably furnished with a perineal bar for counter pressure, the extended limbs being supported by assistants. The assistant holding the uninjured limb abducts it to the normal limit in order that it may serve as a guide, and incidentally to fix the pelvis. The injured limb is first flexed and rotated sufficiently to disengage soft parts that may be interposed between the fragments. It is then completely extended, and the assistant, by direct manual traction, overcomes the shortening, as demonstrated by measurement and by the relation of the trochanter to Nélaton's line, at the same time correcting the outward rotation. Still maintaining steady traction, he then adducts the limb to correspond with its fellow, the operator meanwhile supporting the joint and lifting the thigh upward. The pelvis should now be level and the extended limbs in exact correspondence in every particular. A plaster spica is then applied from the axilla to the toes. This should be carefully adjusted about the pelvis and trochanter. It should completely cover the buttock and be heavily reinforced beneath the joint and thigh, that it may be unyielding to pressure and therefore effective as a posterior splint to hold the limb at its proper plane.

The prolonged plaster bandage maintains complete immobilization during the period of repair, overcoming the shortening and adduction. The adduction prolonged during four to six weeks is of marked importance in aiding the future ability to walk without impairment or limitation of motion. It further protects the patient from much unnecessary suffering on movement, and renders him far more comfortable.

Northwest Medicine, Seattle, Washington

113 Medical Treatment of Goiter. C. W. Sharples, Seattle.
114 Id. F. Epplen, Spokane.

110. **Causation and Prevention of Goiter.**—Reasoning from an abundant clinical experience, it seems reasonable to Brown to suppose that the infective agent or exciting material that causes enlargement of the thyroid gland does not act directly on the gland, but affects the system in such a manner that the gland must hypertrophy or enlarge to satisfy the demand for its peculiar internal secretion. He is convinced that, when the thyroid begins to enlarge there is a state of deficiency of thyroid secretion—hypothyroidism. Thyroid feeding improves the health and reduces in a very marked manner the size of the gland. The prevention of goiter would then resolve itself to purification of domestic water supplies by installation of hypochlorite plants and, perhaps, addition of iodin in minute doses to water for household consumption in goitrous communities. Focal infections of teeth, tonsils, adenoids and sinuses of head should receive prompt and careful treatment, especially in the young. Brown urges that careful search be made for hypothyroidism in the children, as thyroid feeding, if instituted in time, would probably prevent any marked hypertrophy of the thyroid.

111. **Prevalence and Distribution of Goiter in Washington.**—Hall attempted to classify the 3,339 students who entered the University of Washington during the past five years, according to the condition of their thyroid glands. This series consists of 2,086 men with the average age of 20 years and 5 months, and 1,253 women with the average of 19 years and 3 months. Of the 1,253 women, 388 were affected, or practically 31 per cent., as follows: 272 classed as perceptible, or 13.03 per cent.; 92 classed as medium or 4.43 per cent.; 10 classed as large, or 0.48 per cent. Of the 1,253, 388 were affected, or practically 31 per cent., as follows: 294 classed as perceptible, or 23.45 per cent.; 85 classed as medium, or 6.79 per cent.; 9 classed as large, or 0.7 per cent. Averaging men and women together it gives 24.40 per cent., or about one in every four.

Of the nineteen classed as large, four had a marked exophthalmus, one man and three women. In a series of 343 women, of whom 83 were affected, ten, or 2.9 per cent., gave a history of the malady in the family. As to the distribution of the malady, it bears a rather constant relationship to certain geologic conditions. From the standpoint of the soil in the state of Washington, it seems to be confined to that part in which the marine deposits of the eocene and myocene ages are still exposed, namely, all of the state excepting the southeastern corner consisting of the nine contiguous counties. From these nine counties eighty-two examinations were made with only three cases affected, or a percentage of 3.6. The soil of this area is alkaline, but the most interesting fact is that this entire area is covered with volcanic ash and lava. Thus the original surface is covered with a sterile mantle.

125. **Vaginal Hysterectomy in Pelvic Disorders.**—With a very few exceptions of combined operation the only patients now recollected by Shoemaker who have lived and remained well ten to eighteen years after operation for undoubted malignant disease of the uterus, have been a few private patients who have had vaginal hysterectomy, preceded by the thorough use of the actual cautery, and supplemented by such use of hysterectomy clamps as has resulted in necrosis and discharge of much parametrial tissue during convalescence. The longest done was in February, 1896, or eighteen years ago, and the patient is still in good health. The pathologic diagnosis of carcinoma was made by Dr. Henry Cattell. Another patient aged 50, with squamous epithelioma of cervix, pathologic diagnosis made by Dr. Edsall, was operated on in 1898. Examined fourteen years later, she was well. One patient, aged 72 years, with epithelioma of cervix, lived ten years longer and died of old age without signs of recurrence. Another, with carcinoma of endometrium operated on fourteen years ago, is now well, her physician reports. Another was operated on twelve years ago and is now in perfect health. Pathologic diagnosis made by Dr. Beyea, was malignant adenoma of endometrium. Shoemaker states that these patients were seen very early and were cauterized, or they would not have done so well.

5 Perforated Gastric Ulcer. C. W. Cathcart, A. Thomson, H. J. Stiles and Others.
6 Nutritive Diseases of Infancy. J. S. Fowler.

4. **Primary New Growths of Mediastinum.**—Sixty cases were studied by Ross, 85 per cent. were found in persons over the age of 30 years and 70 per cent. between the ages of 30 and 50 years. The extremes were 18 and 70 years. Men were affected much more frequently than women, the proportion being 2.15:1. The sex, however, seemed to have a determinating factor as to the variety of tumor found. While in both sexes sarcoma was the commonest form, in females carcinoma was three times as frequently met with as in males. Males: Carcinoma, 4 cases; sarcoma, 33 cases; unclassified, 4 cases. Females: Carcinoma, 6 cases; sarcoma, 11 cases; unclassified, 2 cases. Only 23.5 per cent. gave a definite malignant family history, while in 31.6 per cent. there was a definite tuberculous family history. In 6.6 per cent. there was both a malignant and a tuberculous history. In 41.6 per cent. definite post-mortem evidence of tuberculosis was found within the chest, but in only two cases were tubercle bacilli actually demonstrated in the sputum.

The common seat of origin was the anterior mediastinum. In 68 per cent. of cases the anterior glands were primarily affected, though in 21 of these the disease had spread to involve the posterior and bronchial glands as well. Of the 44 cases of sarcoma 32 were lymphosarcoma. In 93.3 per cent. of cases the disease spread before death to involve the lung tissue. The right lung was affected in 71.6 per cent. of cases. The commonest combination was found to be an involvement of liver, pancreas and suprarenals. Most of the cases ran a more or less chronic course, and all were fatal. The minimum duration was nine weeks. The maximum duration was eighty-eight weeks. The tendency seemed to be that the younger the patient the more rapid was the course of the illness. The causes of death were: Exhaustion, 43 cases; asphyxia, 11 cases; hemoptysis, 3 cases; cardiac failure, 2 cases; cerebral tumor, 1 case.

The study of these 60 cases of new growth of the mediastinum leads Ross to conclude that malignant disease of the mediastinum is not so rare as is generally supposed, and it seems to be increasing in frequency. The symptomatology is variable. If pyrexia be present, it is due to some complication supervening on, or caused by, the original condition. Microscopic examination of the sputum is rarely of any diagnostic value, but the persistent absence of tubercle bacilli in a case suggesting pulmonary tuberculosis is very significant. Hemoptysis, though moderately common, is rarely severe. A pleural effusion is often present and it is often hemorrhagic, but a hemorrhagic effusion is not pathognomonic of malignant disease. Microscopic examination of the pleural fluid is rarely of any diagnostic significance. A large proportion of lymphocytes is quite as commonly found in a malignant as in a tuberculous effusion. Roentgenography is of great value in the diagnosis.

7. **Modern Aspects of Certain Problems in Pathology of Mental Disorders.**—In the absence of anything approaching adequate information, it seemed desirable to experiment with the blood of certain of the insane with a view to determining whether specific precipitins could be produced by inoculation of rabbits and for this purpose Schölberg and Goodall selected cases of dementia paralytica and dementia praecox; the former presenting well-marked symptoms of the second stage, the latter in an active stage of the disease. Blood was received from an arm vein through a sterile cannula into a sterile bottle, and the serum allowed to separate. Rabbits were inoculated intravenously, in accordance with the practice recommended by Uhlenhuth and Weidanz, at intervals of seven days with from 2.5 to 3.0 c.c. of the serum. Seven days after the third injection and before each subsequent injection, about 3.0 c.c. of blood was removed from the dorsal vein of the ear, centrifugalized, and 0.1 c.c. of the serum added to 1 c.c. of a dilution of 1 in 1,000 (salt solution) of the freshly obtained serum of the patient whose blood was to be tested. The antiserum was thus tested on the seventh day after each injection—that is, about the time at which, according to Uhlenhuth and Beumer, the production of precipitin in the rabbit's blood is most active.

Schölberg and Goodall found that when a precipitate was about to be formed the clear fluid of the tube concerned showed a characteristic cloudiness within a quarter of an hour, but flocculi took longer to appear; and it was from one to three and a half hours before the actual precipitate was apparent. The animal furnishing the precipitin was immediately killed under chloroform, the blood allowed to collect and clot in a sterile bottle, the serum filtered through a porcelain filter and received direct into ampoules, which were sealed as filled. Thirteen patients were examined and ninety-four rabbits were used. Precipitin was formed in 10.6 per cent. or in ten out of the ninety-four instances, illustrating the difficulty met with in the attempt to obtain information about precipitins. A precipitin was mostly obtained after injection of from 8 to 12.5 c.c. of serum, and when the latter amount is exceeded the prospect of obtaining precipitin is small; in fact, it is not worth while to continue with the injections when no result is obtained with, say, 15 c.c. The loss of weight shown in individual instances was very considerable in the majority of the rabbits, and of 89 in which the weight was taken weekly during the inoculations, 73, or 82 per cent., lost weight.

The points brought out are these: Seven antiserums, from rabbits inoculated with serum from cases of dementia paralytica and dementia praecox were employed against the serum of 173 patients, in dilutions varying from 1 to 100 and 1 to 20,000. These patients illustrated many kinds of insanity—two exceptional cases were those of sane persons with florid syphilis, for trial with antiserum from a general paralytic. Each antiserum was put against the serum of the patient by the injection of which it resulted, also against that of patients with the same disease, and against serum of patients with other kinds of insanity.

The results were estimated by naked-eye observation. From these it is to be gathered that a given antiserum produces the same amount of precipitate, whether it be put against the actual serum by which it was produced, the serum of patients suffering from the same disease, or the serum of patients suffering from other kinds of insanity. And this obtains for the various dilutions employed. In ten cases antiserum from a general paralytic was put against cerebrospinal fluid from general paralytics, an imbecile, and a case of delusional insanity, in a dilution of 1 to 500. Either no precipitate or a mere trace resulted and without distinction as regards amount. With the pure cerebrospinal fluid, abundant precipitate resulted, but again without distinction. Evidently the reacting body is much less in amount in this fluid than in the serum.

8. **Radical Cure of Femoral Hernia.**—During the last three years Buckley has performed the following operation some thirty times, no patient having returned with a recurrence. The skin incision is made commencing about 1½ inches

above the inner end of Poupart's ligament and vertically above the crural canal, extending down to 1½ inches below the external opening of the canal and having a slight convexity outward. Buckley prefers the external convexity in that it gives more room and removes the suture line further from the genital organs than does the ordinary straight vertical incision. The hernial sac, covered by its layer of properitoneal fat, is exposed and thoroughly separated as far as the opening of the crural canal into the thigh. The upper end of the wound is held open by retractors, the surface of the aponeurosis of the external oblique muscle cleaned and an incision made in it parallel to its fibers about 2 inches long and ½ inch above the external ring of the inguinal canal. The conjoined tendon is thereby exposed. The properitoneal fat, covering the true sac of the hernia, is now removed as completely as possible.

An opening is made with scissors at the apex of the sac, the contents, if any, are reduced, and any adhesions separated. The edges of the sac are held apart by Spencer Wells forceps, and the forefinger is passed through the crural canal into the abdominal cavity. The finger when passed is flexed forward so that the tip presses against the conjoined tendon. A pair of closed curved "catch" forceps is passed along the flexor surface of the inserted finger until the tip of the forceps is against the conjoined tendon; the tip of the forceps is pushed through the conjoined tendon, and appears at the upper end of the skin incision. The opposed surfaces of the blades of the forceps are grooved, the better to hold a closed pair of Kocher's hernia forceps, the tips of whose blades are inserted between the blades of the curved forceps. The latter are withdrawn with the Kocher forceps in their grip, so that the blades of the latter forceps appear at the opening at the apex of the hernial sac.

The edges of the sac are caught between the blades of the Kocher forceps and the sac is pulled inside out, appearing through the conjoined tendon. This maneuver is carried out gently but firmly, and the peritoneal lining of the crural canal is stripped completely away from the canal and invaginated together with the sac of the hernia. The sac is transfixed with a full-curved needle, threaded with catgut, close to the conjoined tendon, ligatured and then cut away. One end of the catgut is again threaded and the needle passed through the conjoined tendon on one side of the stump, through the stump itself and through the tendon on the other side of the stump, and the two ends tied, the stump thereby being fixed to the conjoined tendon and retraction being prevented. The slit in the aponeurosis of the external oblique muscle is closed with a continuous catgut suture; the pectineus muscle and fascia are brought into apposition with Poupart's ligament by a stout catgut suture; the skin incision is closed with silkworm gut, and a gauze dressing and firm spica bandage applied.

9. **Treatment for Prolapsus Ani in Young Children.**—The principle in the treatment advocated by Gemmill is to bring about a condition in which the abdominal capacity responds passively to the decrease in contents brought about by the evacuating contractions of the large bowel, and is not actively decreased by the strength of the accessory forces. This is attained by preventing the flexion of the thighs and spine. A straight wooden splint, well padded and covered with mackintosh, is applied to the back of the child of a length to reach from the neck to the heels, and the child is fixed to the splint by two bandages, one round the thorax and the other round the lower limbs. Splint with a hiatus in the region of the anus bridged by a circle of iron, allows defecation without soiling of the splint and also easy access for such local treatment as cold douching. The result obtained is that the extended position of the child prevents the action of the accessory forces in great part, for the abdominal muscles are placed at a disadvantage for contracting. This position also prevents the decrease in abdominal capacity from flexion. Hence evacuation takes place almost entirely from the muscular action of the great bowel. The removal also of the natural support which the soft parts give to the anal canal and sphincters is prevented, and the splint itself gives additional local support by pressing on the soft parts of the buttocks, from which it follows that the hiatus must not be too large, a condition in which this local pressure would be lost. The relief which this method gives is immediate, the bowel remaining in the abdomen after reduction from the beginning and no prolapse occurring even during defecation, for which the splint must not be removed.

18 *Phenol in Treatment of Tetanus. P. Sainton.

15. **Treatment of Wounds in War.**—This is a little manual of instructions for the physicians with the French army, prepared by Chavasse, chief of the medical department of the active army. It says that every wound and its vicinity should be painted with a single coat of 1 per cent. tincture of iodin. Soiled dressings must not be thrown on the floor, but into some receptacle. The fact that a dressing smells badly is in itself no reason for changing it. Nothing promotes the healing of a wound so much as to leave it in peace. When the dressings smell offensively they can be deodorized with a tablespoonful of Javelle water (solution of chlorinated potassa) to a liter of water, or a tablespoonful of Labarraque's solution (solution of chlorinated soda) to a liter of water. Trains carrying the wounded should have an ample supply of these deodorants. Another point emphasized is that bandages should not be made up in rooms where there are sick or wounded. Wounds in war should never be closed up, but, when the defect is very large, strips of plaster, clips or other measures partially to close the gap will aid repair later. No constricting band should be left in place for longer than one hour or two at most. Direct compression to arrest hemorrhage is safer than letting a tourniquet stay on too long. Jagged wounds should be cautiously cleared of foreign substances and sterilized with hydrogen dioxid, finishing with tincture of iodin applied throughout the depths to every point. Pure oxygen played in the depths of the wound is an important aid in warding off gas gangrene.

18. **Phenol in Tetanus.**—Sainton says that six patients recovered of his twenty-two with tetanus, and in two the tetanus was of the severest type. His treatment consisted of a subcutaneous injection twice a day of 40 or 50 c.c. of 2 per cent. solution of phenol—the Baccelli method. The patients were isolated in semidarkness, and twice a day each was given an enema containing 6 or 8 gm. of chloral, one or two yolks of eggs and 250 gm. of milk. The phenol injections were kept up for a month or more in two cases, one patient thus receiving a total of 48 and another 88 gm. of the phenol (*acide phénique*). The secret of success, he reiterates, is to commence treatment at the first signs of the slightest difficulty in swallowing or of contracture in the muscles around the wound.

23 *The Swiss Red Cross Unit in Balkan War. (L'activité de l'ambulance Vaud-Genève pendant la guerre gréco-turque.) A. Reverdin.
24 *Prevalence of Cancer in Switzerland in Relation to Soil and Water. J. Barth.

22. **Correction of Retroflexion by Abdominal Fixation of the Uterus.**—Muret analyzes with minute detail 38 cases of this kind in which pregnancy occurred later. The women were between 21 and 35 years old, and the pregnancy developed normally and the head presented in every case. Delivery was spontaneous in 23 of the 31 cases that proceeded to term; forceps were required in 8 and there was premature delivery in 3 cases and 7 of the women aborted. There was never any disturbance from traction on the uterus or displacement of the cervix or abnormal presentation or dystocia requiring version or cesarean section, and the puerperium was normal in all. He fastens the uterus to the abdominal wall very low down on both the uterus and the abdominal wall, and makes the junction superficial and narrow. This allows the uterus to expand without interference with its enlargement or its evacuation later. The proportion of premature deliveries and abortions was no higher than the usual average, he adds.

23. **Work in Field Hospital in Balkan Wars.**—Reverdin's account of the work of the flying hospital sent by Switzerland to the aid of Greece in 1913 is profusely illustrated. The mortality among the wounded rose and fell with the duration and discomfort of the transportation. He says that bullets that rebound from a hard surface are liable to have the shell cracked and thus they mushroom in the tissues. Another factor in explosive action of this kind is the heat generated by the impact against the hard substance; the bullet as it rebounds has become so hot that part of the lead kernel softens. The great difference in favor of abdominal wounds in war, he remarks, "is because the soldiers are not the sedentary, meat-eating, constipated creatures of peace." One of the drawbacks of military surgery is that the wounded pass through two or three different surgeons' hands in the field and clearing and base hospitals, and the plan of treatment thus gets deflected according to the personal bias of each surgeon.

24. **Cancer in Relation to Soil and Water.**—Barth's geologic and meteorologic data and the statistics in regard to the prevalence of cancer show that in the regions with much silica in the soil cancer is comparatively rare. It is twice as frequent in the regions with chalky soil, and especially along the rivers flowing through cretaceous regions. He urges others to investigate the data along these lines in other countries, and adds that Zeller has reported encouraging results from sodium silicate in treatment. Phenomena of mineralization or demineralization from the action of the lime in the cretaceous soil may yet prove to be a factor in the predisposition to cancer.
